CNB WORKING PAPER SERIES

The Working Paper Series of the Czech National Bank (CNB) is intended to disseminate the results of the CNB’s research projects as well as the other research activities of both the staff of the CNB and collaborating outside contributor, including invited speakers. The Series aims to present original research contributions relevant to central banks. It is refereed internationally. The referee process is managed by the CNB Research Department. The working papers are circulated to stimulate discussion. The views expressed are those of the authors and do not necessarily reflect the official views of the CNB.

Welfare-Based Optimal Monetary Policy
in a Two-Sector Small Open Economy

Yuliya Rychalovska *

Abstract

The paper analyzes the stabilization objectives of optimal monetary policy and the trade-offs facing the central bank in a two-sector small open economy model obtained as a limiting case of a two-country DSGE framework. We introduce a more complicated economic structure, namely, multiple domestic sectors combined with a variety of exogenous shocks. In addition, our model includes a more general specification of consumers’ preferences than has been considered in the literature so far. As a result, we are able to uncover additional welfare effects specific to the open multi-sectoral economy and make a methodological contribution by deriving a utility-based welfare measure and the optimal reaction function of the central bank. We show that the optimal targeting rule is represented by a complex expression that prescribes the response to the appropriate measure of domestic inflation, sectoral output gaps, as well as to the relevant relative prices. We demonstrate that our model generates an endogenous conflict between the objectives of domestic inflation and real exchange rate stabilization in addition to the inflation-output gap policy trade-off common in the literature. Furthermore, we experiment with alternative simple rules and analyze their ability to replicate the optimal solution.

Nontechnical Summary

In recent decades the approach to monetary policy conduct has shifted to a more systematic one. Many central banks have formulated their policy objectives explicitly and, more specifically, have announced their commitment to price stabilization as the overriding policy goal. As a result, a new operational framework, i.e., inflation targeting, has been introduced by the most advanced central banks.

The related discussion in academia has been evolving around the issue of whether strict inflation targeting indeed represents the best strategy from the welfare viewpoint. In other words, researchers attempt to define the set of appropriate monetary policy objectives that maximize social welfare. Such an analysis has been performed for different economic models. One thread in the literature derives optimal policy under assumed welfare objectives. In particular, the loss function usually takes the quadratic form with terms such as inflation (CPI or domestic) and the output gap, with weights chosen ad hoc. This approach is very popular in applied research because it greatly simplifies the derivations and brings the model dynamics closer to the real data. At the same time, such an approach assumes certain policy objectives a priori. An alternative methodology analyzes optimal monetary policy on the basis of the objective function of the central bank, which is derived from micro-foundations.

This paper contributes to the second class of literature. We analyze policy objectives that are optimal from the welfare perspective of a small open economy with a traded and non-traded sector. More specifically, our work adds to the normative analysis of open economies by introducing a more complicated economic structure, namely, multiple domestic sectors, combined with a variety of domestic (sector-specific) and foreign shocks. In addition, the general specification of consumers’ preferences (non-unitary elasticity of substitution) is considered. We assess the role of structural asymmetries and multiple relative prices for monetary policy design and welfare evaluation. We derive a utility-based welfare measure and the optimal reaction function of the central bank. For this purpose, linear-quadratic solution methods, which involve computation of a second-order approximation of the utility function and the model structural equations, are employed. This approach enables us to analyze the determinants of optimal monetary policy and rank alternative monetary policy regimes on the basis of a rigorous welfare measure derived from micro-foundations and approximated by a tractable quadratic form.

We find that differentiating production between traded and non-traded goods in an open economy brings sector-specific features into the formulation of social welfare objectives. In addition, the loss function contains an open economy term, i.e., the exchange rate. Therefore, for our model specification, the micro-founded stabilization goals differ from their ad hoc counterparts assumed in the literature. We show that the optimal targeting rule is represented by a complex expression that prescribes the response to the appropriate measure of domestic inflation, sectoral output gaps, as well as to the relevant relative prices, i.e., the exchange rate and the relative price of non-traded goods. Taking into account the complexity of the optimal reaction function, we found it practically important to experiment with alternative simple rules and analyze their ability to replicate the optimal solution. Our numerical results suggest that the type of shock is an important determinant of the comparative performance of optimal versus simple policy rules. Specifically, the optimal response differs the most from the simple rules under fiscal and mark-up shocks. In general, we draw the conclusion that strict targeting of domestic and CPI inflation is not the best approximation for the optimal policy. The reason for such a result is that the optimal policy prescribes a different magnitude of response to changes in home and non-traded inflation rates. Therefore, targeting domestic inflation, which aggregates sector-specific inflations into one variable, is suboptimal. In addition, the social welfare objectives imply a certain degree of output gap and exchange
rate management. The poor performance of CPI targeting can be explained by the excessive smoothness of relative prices which this regime entails.

Furthermore, we rank a set of alternative simple rules according to the derived welfare measure and demonstrate that welfare loss can be reduced by accounting for policy objectives other than inflation, namely, the output gap and the exchange rate. We also evaluate the benefits of targeting sector-specific versus aggregate variables. In addition, we find that inclusion of the exchange rate in the targeting rule may contribute to welfare improvements when the central bank does not have enough information about the sector-specific variables. Generally, the simple rules perform quite well in terms of macroeconomic stabilization and can deliver reasonable welfare results. Finally, the analysis of macroeconomic volatility under the simple rules demonstrates that our model generates tension between the objectives of domestic inflation and real exchange rate stabilization in addition to the inflation-output gap policy trade-off common in the literature. Such an analysis may be of practical importance prior to entering the Eurozone, when the monetary authority has to fulfill several (sometimes conflicting) stabilization objectives.

In this paper we analyzed the optimal monetary policy for a model with a more complex, yet more realistic, economic structure. However, the model remains quite stylized and represents a rather simplified view of the real world. The results are based on a set of assumptions such as Calvo-type price setting, rationality of agents, absence of uncertainties and adjustment costs, etc. Therefore, our analysis may provide rather restricted normative conclusions. Keeping this caveat in mind, we believe, however, that the micro-founded approach enables us to deepen the understanding of the mechanisms and incentives that arise in the real economy and thus to improve policy recommendations.
1. Introduction

In the world of dynamic interactions between economies through international trade, should policymakers account for various country-specific features when implementing monetary strategy, or should they assume that welfare can be maximized under the uniform specification of the policy objectives? In other words, to what extent are the appropriate monetary policy targets endogenous to specific characteristics such as country size, degree of openness, asymmetric economic and trading structure, and the level of development across countries? This paper aims to contribute to the discussion of these crucial issues of monetary policy design and practical implementation.

The importance of taking a systematic approach to the conduct of monetary policy, featuring explicit formulation of policy objectives, has been rising in recent decades. Price stability has been recognized as the overriding policy goal by many monetary institutions worldwide. As a result, a new operational framework has been introduced by the most advanced central banks in order to match the officially stated goals of macroeconomic stabilization with their practical realization. Inflation targeting, which implies a quantitative specification of the desired level of inflation, has gained a reputation as being a strategy capable of generating stable and non-inflationary growth, thus strengthening the policy credibility and reputation of the monetary authority.

However, important features of modern economies, such as the social and economic consequences of unemployment, uncertainties of various types, asymmetric economic structure, and interrelations with the rest of the world, have brought about efforts to widen the range of policy objectives beyond inflation (price) stability alone. Therefore, over the past several years, the attention of leading economists has turned to the issue of formal characterization of the proper monetary policy objectives. These concerns have spurred a variety of research attempting to shed some light on the question of whether strict inflation targeting indeed represents the optimal monetary policy from the welfare viewpoint. Addressing this topic is the most challenging when analyzing open economy models, where the formulation of policy targets appears to be more controversial compared to a closed economy setting.

The central issue in the literature on open economies is the assessment of the implications of openness for the formulation of the central bank’s policy objectives and welfare analysis. In other words, the underlying questions are whether the central bank should also target open economy variables, i.e., the exchange rate, and how the targeting of domestic variables changes under the exposure of the economy to external factors. Answering these questions involves studying the conditions under which the open economy problem is not isomorphic to the closed economy model specification. Another topic which has attracted a great deal of attention from both researchers and practitioners is related to the determination of the appropriate inflation measure that has to be stabilized.

The problem of formal welfare analysis and characterization of optimal monetary policy rules for different economic models has been addressed in a number of studies. It has been shown that welfare-maximizing monetary policy in a closed economy should aim to stabilize both CPI inflation and the output gap. Woodford (2003) derives the corresponding loss function from the utility of the representative household. In studies of open economies, ranking of alternative monetary regimes and policy rules has been extensively performed on the basis of ad hoc objective functions or, alternatively, welfare representations derived for closed economy models.

A surprising conclusion drawn by several authors who have performed explicit welfare derivation for models of open economies is that exchange rate fluctuations have no direct impact on welfare. Specifically, Clarida, Gali, and Gertler (2001) find that under perfect exchange rate pass-through, the qualitative
results for the closed economy carry over to the open economy. Gali and Monacelli (2005), who characterize the welfare of a small open economy for a special case of parameter values and under the balanced trade assumption, support the previous result and conclude that the small open economy problem is identical to that of a closed economy. The above results taken at face value imply optimality of complete exchange rate flexibility.

However, a number of recent studies have challenged this finding. Specifically, Corsetti and Pesenti (2005), Sutherland (2002), and Monacelli (2003) show that under incomplete pass-through, optimal policy is not purely inward looking. Benigno and Benigno (2006) analyze the gains from international monetary policy cooperation. They study the conditions under which individual countries have incentives to influence the terms of trade and thus to deviate from the socially optimal point. De Paoli (2006) finds that the simple violation of purchasing power parity (PPP) which arises from home bias in consumption brings in a role for targeting the real exchange rate in a one-sector small open economy model. Liu and Pappa (2005) consider a two-sector open economy model in a two-country framework. Their study provides interesting insights into the impact of asymmetric structure between sectors on the gains from cooperation. Their results suggest that in an economy with multiple sectors, and thus multiple sources of nominal rigidities, optimal monetary policy cannot replicate a flexible price allocation creating the scope for coordination. The important limitation of their work for the analysis of optimal monetary policy is the assumption of unitary elasticity of substitution across goods and a logarithmic utility function. As a result, under this very special case important welfare effects vanish and general conclusions concerning the optimal monetary policy cannot be derived.

The theoretical contributions discussed above mainly address the issue of the optimal monetary policy in stylized model frameworks that are derived from micro-foundations, but, at the same time, they represent rather a simplified view of the real economy. Factors such as uncertainties, transmission mechanism lags, adjustment costs, and other country-specific characteristics are difficult to take into account in this class of models. Therefore, an alternative methodological approach, which allows the incorporation of more realistic features of real economies into the model, is now widely used in the literature and practice of central banks. This approach implies the derivation of the optimal policy rules on the basis of reduced-form model equations and an ad-hoc welfare function. Among the relevant contributions in the field is the paper by Hlédik (2003), who investigates the second-round effects of selected supply-side shocks and of shocks to the nominal exchange rate on wages and inflation. The author analyzes the optimal reaction of the central bank to these shocks and derives the optimal policy rules within the New-Keynesian framework. The reduced form approach employed in this paper allows us to incorporate a realistic (for the Czech economy) specification of wage contracts, to account for the delayed effects of monetary policy, and to include backward-looking components into the model. Consequently, the dynamics of the model are more realistic, which makes the results of such an analysis and the approach in general extremely useful for practical purposes.

Our work aims to analyze the stabilization objectives of optimal monetary policy and the trade-offs facing the central bank in a two-sector small open economy model obtained as a limiting case of a two-country Dynamic Stochastic General Equilibrium framework. We assess the role of general preferences, structural asymmetries, and multiple relative prices for monetary policy design and welfare evaluation.

Specifically, we aim to contribute to the normative analysis of open economies by introducing a more complicated economic structure, namely, multiple domestic sectors combined with a variety of sector-specific and foreign shocks. In addition, we consider a general specification of preferences. These features of the model differentiate our work from the previous studies, which derived their results for the special cases of unitary elasticity of substitution across goods or, alternatively, relied on the ad hoc
objective functions and welfare representations obtained for closed economy models. By abstracting from those simplifying assumptions we are able to uncover additional welfare effects specific to the open multisectoral economy and make a methodological contribution by deriving the utility-based welfare measure and the optimal reaction function of the central bank under more generalized preferences. For this purpose we employ the linear-quadratic solution methods discussed in Benigno and Benigno (2006) and Benigno and Woodford (2005), which involve computation of a second-order approximation of the model structural equations. This approach enables us to analyze the determinants of optimal monetary policy and rank alternative monetary policy regimes on the basis of a rigorous welfare measure derived from micro foundations and approximated by a tractable quadratic form.

The results of our study support the conclusion drawn by Benigno and Benigno (2006) and De Paoli (2006) that the optimal monetary policy for an open economy, in general, is not isomorphic to the one prescribed for the closed economy. Unlike the contributions mentioned above, our findings are determined by a multisectoral economic structure and, in particular, by the various sensitivities of the domestic sectors to exogenous shocks. We find that differentiating production between traded and non-traded goods in the open economy generates important implications for optimal policy and welfare. While in the closed economy setting the best strategy is determined purely by structural characteristics such as sector size or degree of nominal rigidities, the open economy formulation implies, in addition, openness to trade of one of the domestic segments. Such a qualitative difference between sectors determines their asymmetric response to exogenous shocks (even of identical magnitude) and brings sector-specific features into the formulation of stabilization objectives.

Moreover, our model representation provides important insights into the relevant policy trade-offs. In particular, we show that introducing the non-traded sector into the setup with general preferences allows modeling of the endogenous conflict between the objectives of inflation and exchange rate stabilization in addition to the inflation-output gap policy trade-off common in the literature. We would like to emphasize that under the special case of unitary elasticity of substitution and logarithmic utility, as in the two-sector model by Liu Pappa (2005), only the standard inflation-output gap trade-off can be generated. Thus the crucial role of multiple relative prices in modeling another empirically appealing policy challenge disappears. Furthermore, we derive the optimal targeting rule, which determines the variables (targets) to which the central bank should respond in order to achieve efficient allocation of resources, as well as the magnitude of such a response. We show that the optimal targeting rule is represented by a complex expression that involves backward and forward-looking components. In general, the rule prescribes the response of the central bank to the appropriately specified measure of domestic inflation, sectoral output gaps, as well as to the relevant relative prices, i.e., the exchange rate and the relative price of non-traded goods.

Finally, we experiment with alternative simple rules and analyze their ability to replicate the optimal solution. Such an exercise enables us to explicitly demonstrate and numerically evaluate policy trade-offs in terms of macroeconomic volatility. Our results suggest that targeting domestic inflation is not always the best approximation for the optimal policy, and social welfare can be improved by accounting for other policy objectives, namely, the output gap and the exchange rate. We present a ranking of alternative simple rules, which indicates the costs of implementing alternative monetary strategies and can provide useful information for managing the conflicting policy objectives. We show that the simple rules which stabilize sector-specific variables can be closely replicated by rules that respond to the aggregate output gap and the exchange rate with the appropriate decomposition of weights. Such a result is important because a strategy which differentiates the response between domestic sectors is difficult to design and implement in practice. Generally, the simple rules perform quite well in terms of macroeconomic stabilization (relative to the optimal rule) and can deliver reasonable welfare results.
The paper is organized as follows. Section 2 presents the model and section 3 describes the equilibrium dynamics. Section 4 analyzes the monetary policy problem and welfare. Section 5 describes the results of the numerical simulation. Section 6 illustrates the welfare implications of alternative simple rules. Finally, the results of the paper are summarized in section 7.

2. A two-Sector Small Open Economy Model

The framework is represented by a two-country dynamic general equilibrium model where both sides, Home (the open economy – $H$) and Foreign (the rest of the world, the relatively closed economy – $F$), are explicitly modeled. The small open economy problem is derived as a limiting case of such a framework (as in De Paoli, 2006). Each country has two domestic sectors, which produce traded and non-traded goods; the share of non-traded goods may vary in the consumption basket of each country. A continuum of infinitively lived households consumes the final consumption good, which includes goods produced in both domestic sectors as well as imported goods. Households produce differentiated intermediate goods and receive disutility from production. We introduce monopolistic distortion and sticky prices in both sectors. These assumptions represent the standard way of introducing the role for monetary policy into such class of models. Households as consumers maximize their utility and solve the optimal price-setting problem as producers.

The model specification allows us to consider the closed economy, the open one-sector economy, and the economy with unitary elasticity of substitution as special cases of our more general analysis. We assume sector-specific productivity, fiscal, and mark-up shocks; the degree of nominal rigidities may also differ across sectors. Furthermore, we assume production subsidies in order to offset the monopolistic distortions in both sectors. The international and domestic asset markets are complete.

2.1 Representative Households

In our two-country framework a continuum of domestic households belong to the interval $[0, n)$, while foreign agents belong to the segment $(n, 1]$. The utility function of a representative consumer in country $H$ or $F$ is given by:

$$U_t^j = E_t \left\{ \sum_{s=t}^{\infty} \beta^{s-t} [U(C_t^j) - V(y_{s,T}(j), A_{s,T}^j) - V(y_{s,N}(j), A_{s,N}^j)] \right\}$$

where $j$ is the index specific to the household, and $i$ is the country index; $E_t$ denotes the expectation operator conditional on the information set at time $t$, and $\beta$ is the intertemporal discount factor. $U(.)$ represents the flows of utility from consumption of a composite good and $V(.)$ stands for the flows of disutility from production of differentiated goods. Each household produces two types of differentiated goods – traded and non-traded. The home economy produces a continuum of differentiated traded goods indexed on the interval $[0, n]$, whereas the foreign economy’s traded goods belong to the interval $(n, 1]$. In addition, a continuum of differentiated non-traded goods are indexed on the interval $[0, n]$ and $(n, 1]$ for the home and foreign country, respectively. $\Lambda$ denotes a productivity shock that can be country and sector specific. The subscript $T$ stands for the traded sector, whereas $N$ denotes the non-traded sector.

In our analysis we assume that preferences have isoelastic functional form:

$$U(C_t^j) = \frac{(C_t^j)^{1-\rho}}{1-\rho}, \quad V(y_{s,L}(j), A_{s,L}^j) = \frac{(A_{s,L}^j)^{-\eta}(y_{s,L}(j))^{1+\eta}}{1+\eta},$$
where \( L = H, N; \rho > 0 \) is the inverse of the intertemporal elasticity of substitution in consumption, and \( \eta \geq 0 \) is equivalent to the inverse of the elasticity of goods production. The composite consumption good \( C \) is a Dixit-Stiglitz aggregator of traded and non-traded goods defined as:

\[
C^j = \left[ \gamma \frac{1}{\omega} \left( C^j_N \right)^{\frac{\omega-1}{\omega}} + \left( 1 - \gamma \right) \frac{1}{\omega} \left( C^j_T \right)^{\frac{\omega-1}{\omega}} \right]^{\frac{1}{\omega-1}}
\]

where \( C_N \) and \( C_T \) are the consumption sub-indexes that refer to the consumption of non-traded and traded goods, respectively, \( \omega > 0 \) is the intratemporal elasticity of substitution, and \( \gamma \) is a preference parameter that measures the relative weight that individuals put on non-traded goods.

Preferences for the rest of the world are specified in a similar fashion:

\[
C^{j*} = \left[ (\gamma^*) \frac{1}{\omega} \left( C^{j*}_N \right)^{\frac{\omega-1}{\omega}} + \left( 1 - \gamma^* \right) \frac{1}{\omega} \left( C^{j*}_T \right)^{\frac{\omega-1}{\omega}} \right]^{\frac{1}{\omega-1}}
\]

where the asterisk denotes a foreign country variable.

Traded consumption goods are the aggregators of goods produced at home and abroad and defined as:

\[
C^j_H = \left[ \frac{1}{n} \int_0^1 c_H(z) \frac{dz}{\sigma} + \left( 1 - \frac{1}{n} \right) \int f(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C^j_F = \left[ \frac{1}{n} \int_0^1 c_F(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

where \( \sigma > 1 \) is the elasticity of substitution across the differentiated goods.

As in Sutherland (2002) and De Paoli (2006) we assume that \( v^* \), the share of imported goods from country \( H \) in the consumption basket of country \( F \), increases proportionally to the relative size of the home economy \( n \) and the degree of openness \( \tilde{v}^* \). Thus we assume that \( v^* = n \cdot \tilde{v}^* \). Similarly, \( (1 - v) = (1 - n) \cdot \tilde{v} \). Such a specification allows modeling of home bias in consumption as a consequence of different country size and degree of openness.

The consumption sub-indexes of non-traded, home-produced, and foreign-produced differentiated goods are defined as follows:

\[
C_N = \left[ \frac{1}{n} \int_0^1 c_N(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C^*_N = \left[ \frac{1}{n} \int_0^1 c^*_N(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C_H = \left[ \frac{1}{n} \int_0^1 c_H(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C^*_H = \left[ \frac{1}{n} \int_0^1 c^*_H(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C_F = \left[ \frac{1}{n} \int_0^1 c_F(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

\[
C^*_F = \left[ \frac{1}{n} \int_0^1 c^*_F(z) \frac{dz}{\sigma} \right]^{\frac{1}{\sigma - 1}},
\]

where \( \sigma > 1 \) is the elasticity of substitution across the differentiated goods.
Thus the real exchange rate is not equal to one and is defined as

$$P = \gamma P_N^{1-\omega} + (1 - \gamma) P_T^{1-\omega} \left( \frac{1}{1-\sigma} \right)$$  \hspace{1cm} (1)

$$P^*_T = \nu P_H^{1-\theta} + (1 - \nu) P_F^{1-\theta} \left( \frac{1}{1-\sigma} \right)$$  \hspace{1cm} (1a)

$$P^* = \left[ (\gamma^*) (P_N^*)^{1-\omega} + (1 - \gamma^*) (P_T^*)^{1-\omega} \right] \left( \frac{1}{1-\sigma} \right)$$  \hspace{1cm} (2)

$$P^*_F = \left[ (\nu^*) (P_H^*)^{1-\theta} + (1 - \nu^*) (P_F^*)^{1-\theta} \right] \left( \frac{1}{1-\sigma} \right)$$  \hspace{1cm} (2a)

The price sub-indexes for home, foreign, and non-traded goods in the two economies are:

$$P_N = \left[ \left( \frac{1}{n} \right) \int_0^n p_N(z) \right] ^{1/\sigma} \left[ \left( \frac{1}{1-n} \right) \int_n^1 p_N(z) \right] ^{1/(1-\sigma)}$$

$$P_H = \left[ \left( \frac{1}{n} \right) \int_0^n p_H(z) \right] ^{1/\sigma} \left[ \left( \frac{1}{1-n} \right) \int_n^1 p_H(z) \right] ^{1/(1-\sigma)}$$

$$P_F = \left[ \left( \frac{1}{n} \right) \int_0^n p_F(z) \right] ^{1/\sigma} \left[ \left( \frac{1}{1-n} \right) \int_n^1 p_F(z) \right] ^{1/(1-\sigma)}$$

where \( p_N(z) \), \( p_H(z) \), and \( p_F(z) \) are prices in units of the domestic currency of the home-produced non-traded and traded goods, and foreign-produced goods. The law of one price holds for differentiated goods, i.e., \( p_h(z) = S \cdot p_N^h(z) \) and \( p_f(z) = S \cdot p_N^f(z) \), where \( S \) is the nominal exchange rate, defined as the price of the foreign currency in terms of the domestic currency. This in turn implies that \( P_H = S \cdot P^*_H \) and \( P_F = S \cdot P^*_F \). However, equations (1) and (2) demonstrate that the presence of non-traded goods and the home bias in consumption result in violation of the Purchasing Power Parity (PPP), i.e., \( P \neq S \cdot P^* \). Thus the real exchange rate is not equal to one and is defined as \( ER = \frac{S \cdot P^*}{P} \). The real exchange rate determinants will be more explicitly analyzed in subsection 2.5.

### 2.2 Aggregate Demand

By solving the consumer’s cost minimization problem we derive the total demand for the differentiated goods produced in countries \( H \) and \( F \) as well as the demand for the non-traded goods in both countries. The resulting demand equations for country \( H \) take the following form:

$$y_H^d(z) = \left( \frac{p_H(z)}{P_H} \right)^{-\sigma} \left( \frac{P_T}{P} \right)^{-\omega} \times \left( \frac{1}{ER} \right)^{-\omega} \times \left[ \left( \frac{P_H}{P_T} \right)^{-\theta} \times \left( \frac{P_T}{P} \right)^{-\gamma} \times C + \right]$$

$$y_H^d(z) = \left( \frac{p_N(z)}{P_N} \right)^{-\sigma} \left( \frac{P_N}{P} \right)^{-\omega} \times \left[ \left( \frac{P_N}{P} \right)^{-\gamma} \times C \right] + G_H$$

$$y_N^d(z) = \left( \frac{p_N(z)}{P_N} \right)^{-\sigma} \left( \frac{P_N}{P} \right)^{-\omega} \times \left[ \left( \frac{P_T}{P} \right)^{-\gamma} \times C \right] + G_N$$

$$y_F^d(z) = \left( \frac{p_F(z)}{P_F} \right)^{-\sigma} \left( \frac{P_F}{P} \right)^{-\omega} \times \left[ \left( \frac{P_T}{P} \right)^{-\gamma} \times C \right] + G_F$$

$$y_F^d(z) = \left( \frac{p_F(z)}{P_F} \right)^{-\sigma} \left( \frac{P_F}{P} \right)^{-\omega} \times \left[ \left( \frac{P_T}{P} \right)^{-\gamma} \times C \right] + G_F$$
and for goods produced in country F:

\[
y^*_f(z) = \left( \frac{p_f(z)}{P_F} \right)^{-\sigma} \left[ \left( \frac{P_F}{P_F} \right)^{-\omega} \left( \frac{P_F}{P_F} \right)^{-\theta} \times \left\{ \left( 1 - \frac{1}{P_F} \right)^{-\omega} \left[ \frac{1}{(1 - \gamma)^{\frac{1}{1 - \gamma}}} \right]^\frac{\theta - \omega}{1 - \theta} \right\} + G_F^* \right] (1 - \gamma^*) (1 - v^*) C^*
\]

(5)

\[
y^*_N(z) = \left( \frac{P_N(z)}{P_N} \right)^{-\sigma} \left[ \left( \frac{P_N}{P_N} \right)^{-\omega} \gamma^* C^* + G_N^* \right]
\]

(6)

where \( G \) and \( G^* \) are country and sector-specific government purchase shocks, \( P_{FH} = \frac{P_F}{P_H} \) is the relative price of foreign to home-produced goods, i.e., the terms of trade, and \( ER \) is the real exchange rate.

In order to obtain the small open economy version of our general two-country framework we apply the assumptions \( v^* = n \cdot \tilde{v}^* \) and \( (1 - v) = (1 - n) \cdot \tilde{v}^* \) and take the limit \( n \to 0 \) similar to De Paoli (2006). As a result, the demand equations can be simplified to:

\[
y^*_h(z) = \left( \frac{p_h(z)}{P_H} \right)^{-\sigma} \left[ \left( \frac{P_H}{P_H} \right)^{-\omega} \left( \frac{P_H}{P_H} \right)^{-\theta} \times \left\{ \left( \frac{1}{P_H} \right)^{-\omega} \left[ \frac{1}{(1 - \gamma)^{\frac{1}{1 - \gamma}}} \right]^\frac{\theta - \omega}{1 - \theta} \right\} + G_H \right]
\]

(7)

\[
y^*_f(z) = \left( \frac{p_f(z)}{P_F} \right)^{-\sigma} \left[ \left( \frac{P_F}{P_F} \right)^{-\omega} \left( \frac{P_F}{P_F} \right)^{-\theta} \times \left\{ \left( \frac{1}{P_F} \right)^{-\omega} \left[ \frac{1}{(1 - \gamma)^{\frac{1}{1 - \gamma}}} \right]^\frac{\theta - \omega}{1 - \theta} \right\} + G_F^* \right]
\]

(8)

Therefore, the demand side for our two-sector small open economy model is represented by equations (4), (6), (7), and (8).

The demand equations illustrate the small open economy implications, the impact of the economic structure, and a more general specification of preferences. In particular, the demand for goods produced at Home depends on both domestic and foreign consumption, whereas the demand for foreign-produced goods is not affected by changes in Home consumption. Moreover, the two-sector model specification brings in the differentiated impact of the terms of trade and the real exchange rate on the total demand for tradable goods. This happens under the general assumption that \( \theta \neq \omega \). The literature on open economies usually assumes that \( \theta > \omega \), \( \theta > 1 \), and \( \omega \) is small. This implies that non-traded and traded goods are complements in the consumption basket. At the same time, home and foreign-produced goods are considered as substitutes.

### 2.3 International Risk Sharing

Foreign and domestic households have access to the international financial market, where state-contingent nominal bonds are traded. Households at home and abroad make their optimal consumption-saving decisions. They maximize their utility subject to the sequence of budget constraints for \( t = 0, 1, \ldots \):

\[
P_t C_t + E_t D_{t,t+1} B_{t+1} \leq B_t + \Pi_t + T_t
\]
where \( B_{t+1} \) is the holding of a nominal state-contingent bond that pays one unit of home currency in period \( t + 1 \), \( D_{t,t+1} \) is the period \( t \) price of the bond, \( \Pi_t \) is the profit income from goods production, and \( T_t \) is the transfer from the government. The complete-market assumption implies that the marginal rate of substitution between consumption in the two countries is equalized:

\[
\frac{U_C(C_{t+1}^*)}{U_C(C_t^*)} \frac{P_{t+1}^*}{P_t} = \frac{U_C(C_t)}{U_C(C_t)} \frac{P_t}{P_{t+1}}
\]

The international risk-sharing equation presented above illustrates the equality of nominal wealth in both countries in all states and time periods. The violation of PPP implies that fluctuations in the real exchange rate may result in divergence in consumption across countries even under optimal risk sharing.

### 2.4 Optimal Pricing Decisions

Each household is a monopolistic producer of one differentiated traded and one non-traded good. The domestic household sets the price \( p_N(z) \) and \( p_h(z) \) and takes as given \( P, P_N, P_H, P_F, \) and \( C \). The price-setting behavior is modeled according to Calvo (1983). In countries \( H \) and \( F \) in each time period a fraction \( \alpha_L \in [0, 1] \) of randomly picked producers in each sector \( (L = N, H) \) are not allowed to change their prices. Thus the parameter \( \alpha_L \) reflects the level of price stickiness. The remaining fraction \( (1 - \alpha_L) \) can choose the optimal sector-specific price by maximizing the expected discounted value of profits:

\[
E_t \sum_{S=t}^{\infty} (\alpha_L \beta)^{S-t} \left[ \frac{U_C(C_S)}{P_S} (1 - \tau_S) \tilde{P}_{t,L}(z) \tilde{y}_{t,S,L}(z) - V(\tilde{y}_{t,S,L}(z), A_{S,L}) \right]
\]

where after-tax revenues in each sector are evaluated using the marginal utility of nominal income, \( \frac{U_C(C_S)}{\tau_S} \), which is identical for all households in the country under the assumption of complete markets; \( \tau_S \) is the tax rate; \( \tilde{P}_{t,L}(z) \) is the price of the differentiated good \( z \), which is produced in sector \( L \), chosen at time \( t \), and \( \tilde{y}_{t,S,L}(z) \) is the total demand for good \( z \), produced in sector \( L \), at time \( S \), conditional on the fact that the price \( \tilde{P}_{t,L}(z) \) has not been changed. All producers who belong to the fraction \( (1 - \alpha_L) \) choose the same price.

The optimal price \( \tilde{P}_{t,L}(z) \), which is derived from the first-order conditions, takes the following form:

\[
\tilde{P}_{t,L}(z) = \frac{E_t \sum_{S=t}^{\infty} (\alpha_L \beta)^{S-t} V(\tilde{y}_{t,S,L}(z), A_{S,L}) \tilde{y}_{t,S,L}(z)}{E_t \sum_{S=t}^{\infty} (\alpha_L \beta)^{S-t} \frac{U_C(C_S)}{P_S} \mu_{S,L} \tilde{y}_{t,S,L}(z)}
\]

where \( \mu_{S,L} = \frac{\sigma}{1 - \tau_{S,L}(\sigma - 1)} \) represents the overall degree of monopolistic distortion and leads to an inefficient gap between the marginal utility of consumption and the marginal disutility of production. Benigno and Benigno (2006) and De Paoli (2006) refer to this gap as the mark-up shock. Calvo-type setting implies the following law of motion for the sectoral price indexes:

\[
P_{L,t} = [\alpha_L (P_{L,t-1})^{1-\sigma} + (1 - \alpha_L) \tilde{P}_{t,L}(z)^{1-\sigma}]^{\frac{1}{1-\sigma}}
\]

Similar conditions can be derived for the producers in country \( F \).
2.5 Real Exchange Rate Decomposition and PPP Violation

In order to explore the structural economic factors that result in PPP violation, we consider the real exchange rate decomposition. The real exchange rate is defined as $ER = \frac{S \cdot P^*_F}{P_H}$. We use the price indexes (1), (1a), (2), and (2a) to express the real exchange rate as a function of relative prices and preference parameters. We also use the fact that the law of one price holds for tradable goods, i.e., $P_H = S \cdot P^*_H$ and $P_F = S \cdot P^*_F$. The real exchange rate can be presented as:

$$ER = \left( \frac{v^* + (1-v^*)(P_{FH}^{1-\theta})}{v + (1-v)(P_{FH}^{1-\theta})} \right)^{\frac{1}{\gamma}} \left( \frac{\gamma^*(P_{NT}^{1-\omega}) + (1 - \gamma^*)}{\gamma P_{NT}^{1-\omega} + (1 - \gamma)} \right)^{\frac{1}{1-\omega}} \cdot (12)$$

where $P_{FH}$ is the terms of trade defined in the previous sections, and $P_{NT} = \frac{P_N}{P_T}$ and $P_{NT} = \frac{P_{NT}^*}{P_{NT}^*}$ are the relative prices of non-traded goods in the two countries. Such a decomposition enables us to analyze the different channels of PPP violation. First of all, we note that under $v \neq v^*$, the $ER$ is affected by the terms of trade. For our small open economy model specification, given the assumptions on $v$ and $v^*$, the difference in country size necessarily results in different shares of consumption of home-produced goods in countries H and F. This so-called home bias channel has also been analyzed by De Paoli (2006) and Sutherland (2002).

Another important component that explains the deviation of the $ER$ from PPP is determined by the multisectoral economic structure. Specifically, different preferences for consumption of non-traded goods across countries, i.e., $\gamma \neq \gamma^*$, as well as changes in the relative price of non-traded goods determine the fluctuation in the $ER$. The divergence in relative prices may occur as a result of country or sector-specific productivity shocks. Moreover, the law of one price holds for traded goods only. Nothing can ensure that the same equality will hold for the goods produced in the non-traded sector. Therefore, the exchange rate in our model is a composite term of two types of relative prices. As far as the policy issues are concerned, such a distinction implies more a difficult task of exchange rate management.

3. Equilibrium Dynamics

The equilibrium is described by the allocations of $C_{H,t}$, $C_{F,t}$, $C_{N,t}$, $B_{t+1}$ and $C^*_H$, $C^*_F$, $C^*_N$, $B^*_{t+1}$ for domestic and foreign households, respectively; the allocations of $y_{t,N}(z)$ and price $\tilde{p}_{t,N}(z)$ for non-traded goods produced in country H and $y^*_{t,N}(z)$, $\tilde{p}^*_{t,N}(z)$ for the intermediate goods produced in country F; the allocations $y^*_{t,H}(z)$ and price $\tilde{p}_{t,H}(z)$ for traded goods produced in the domestic economy, and $y^*_{t,F}(z)$, $\tilde{p}_{t,H}(z)$ for traded goods produced abroad; prices $D_{t,t+1}$, $S_t$, $ER_t$, $P_{t,N,t}$, $P_{t,T,t}$, $P_{H,t}$, $P_{N,t}$, $P_{T,t}$, $P^*_H$, $P^*_N$, $P^*_T$, that satisfy the following equilibrium conditions:

1. taking prices as given, the household’s allocation in each country solves the consumer’s utility maximization problem;

2. taking aggregate prices as given, the demand allocations and the price of each non-traded differentiated good solve the producer’s profit maximization problem;

3. taking aggregate prices as given, the demand allocations and the price of each traded differentiated good solve the producer’s profit maximization problem;

4. the world bond market clears.
3.1 Sticky Price Equilibrium

The equilibrium dynamics under sticky prices are characterized by the optimality conditions derived in section 2. Here we present a log-linearized version of the model. We define \( \hat{x}_t \equiv \ln \frac{x^*}{x} \) as the log deviation of the equilibrium variable \( x_t \) under sticky prices from its steady state value. \( \hat{x}_t^{\text{flex}} \equiv \ln \frac{x^{\text{flex}}}{x} \) represents the log deviation of the equilibrium variable \( x_t \) under flexible prices from its steady state value. Under the assumption of flexible prices, producers can re-optimize every period so that their pricing decisions are synchronized. As a result the price index in each sector is equal to the price set by each producer in this sector and the main source of domestic distortion is eliminated. We will refer to \( \hat{x}_t - \hat{x}_t^{\text{flex}} \) as the deviation of the variable \( \hat{x}_t \) from its natural level, i.e., the gap. At the same time, Benigno and Woodford (2005) and De Paoli (2006) demonstrate that under certain conditions, the flexible price equilibrium does not represent the most efficient allocation of resources, and the desired levels of variables which the policymaker wishes to achieve in order to eliminate the loss may differ from the flexible price allocation. Specifically, in the presence of mark-up and fiscal shocks as well as the condition \( \rho \theta \neq 1 \), the flexible price allocation diverges from the desired targets. Therefore, in general, the optimal policy aims at stabilization of the variables relative to their target level. Thus, we define the welfare relevant gap as \( \hat{x}_t - \hat{x}_t^T \), where \( \hat{x}_t^T \) is the target level of the variable \( \hat{x}_t \). Both the flexible price equilibrium and the target variables are functions of shocks that affect the economy.

Moreover, we define the price change in the traded sector as \( \Pi_H = \frac{P_{H,t}}{P_{H,t-1}} \), and that in the non-traded sector as \( \Pi_N = \frac{P_{N,t}}{P_{N,t-1}} \); consequently, the producer price inflation rates in the traded and non-traded sectors are \( \pi_{H,t} \equiv \ln \left( \frac{P_{H,t}}{P_{H,t-1}} \right) \) and \( \pi_{N,t} \equiv \ln \left( \frac{P_{N,t}}{P_{N,t-1}} \right) \), respectively.

3.1.1 The Steady State

We approximate the model around the steady state, in which \( \overline{A}_N = \overline{A}_H = 1, \overline{C} = 0, \overline{\mu}_H \geq 1, \overline{\mu}_N \geq 1 \). We assume that producer prices do not change in the steady state, i.e., \( \Pi_H = \frac{P_{H,t}}{P_{H,t-1}} = 1 \) and \( \Pi_N = \frac{P_{N,t}}{P_{N,t-1}} = 1 \) at all times. The optimal risk-sharing condition implies that \( E\pi_t = \frac{U_C(C_t^*)}{U_C(C_t)} k_o \). Under the given functional forms, we obtain the condition for the steady state: \( E\pi = \left( \frac{C}{\overline{C}} \right)^{-\rho} k_o \). By choosing \( k_o = \left( \frac{\overline{C}}{C} \right)^{\rho} \) we obtain the steady state real exchange rate equal to unity, i.e., \( E\pi = 1 \). We normalize the price indexes of traded goods at home and abroad so that \( P_H = P_F \), as usually assumed in the literature, i.e., in the steady state the terms of trade \( P_{F_H} \) are equal to unity. Moreover, from the price index equation (1a) it follows that \( P_H = P_T \). We can write the general price index (1) as: \( 1 = [\gamma \overline{P}_N^{1-\omega} + (1-\gamma) \overline{P}_T^{1-\omega}]^{\frac{1}{1-\omega}} \) where \( \overline{P}_N = \overline{P}_N, \overline{P}_T = \overline{P}_T \). From this relation we obtain \( \overline{P}_N = \overline{P}_T = \overline{P} \). The price index equations and the fact that \( E\pi = 1 \) imply that in the steady state prices at home and abroad are equalized. Furthermore, the price setting equations imply the following relationships in the steady state:

\[
U_C(C) \frac{P_H}{P} = \overline{\mu}_H V_g(\overline{Y}_H) \tag{13}
\]

\[
U_C(C) \frac{P_N}{P} = \overline{\mu}_N V_g(\overline{Y}_N) \tag{14}
\]

From the aggregate demand equations (7) and (4) we obtain:

\[
\overline{Y}_H = \left[ (1-\gamma)\overline{\nu} \overline{C} + (1-\gamma^*)\overline{\nu}^* \overline{C} \right] \tag{15}
\]
Moreover, from the price index relation (1a) we note that:

\[ \gamma N = \gamma C \]  

(16)

The world aggregate resource constraint is given by: \( \gamma + \gamma^* = C + C^* \). Combining this condition with (15) and (16) we obtain:

\[ \frac{C}{C^*} = \frac{(1 - \gamma^*)\hat{C}^*}{(1 - \gamma)(1 - v)} \]  

(17)

This relation demonstrates that even under the complete market assumption, the structural asymmetries result in a wedge between consumption in the two countries. Finally, \( k_o = \left( \frac{C}{C^*} \right)^{-\rho} = \left( \frac{(1 - \gamma^*)\hat{C}^*}{(1 - \gamma)(1 - v)} \right)^{-\rho} \).

### 3.1.2 Log-Linearization of the Optimality Conditions

We log-linearize the equilibrium conditions (4), (6)–(10), and (12) and obtain the following set of log-linear equations describing the dynamics of the multisectoral small open economy:

\[ \pi_{H,t} = k_H \left( \eta \hat{Y}_{H,t} + \rho \hat{C}_t + (1 - v)\hat{P}_{FH,t} + \gamma \hat{P}_{NT,t} + \hat{\mu}_{H,t} - \eta \hat{A}_{H,t} \right) + \beta E_t \pi_{H,t+1}, \]  

(18)

\[ \pi_{N,t} = k_N \left( \eta \hat{Y}_{N,t} + \rho \hat{C}_t - (1 - \gamma)\hat{P}_{NT,t} + \hat{\mu}_{N,t} - \eta \hat{A}_{N,t} \right) + \beta E_t \pi_{N,t+1}, \]  

(19)

\[ \hat{Y}_{H,t} = -[\theta + (\theta - \omega)v] \hat{P}_{HT,t} + \omega \gamma \hat{P}_{NT,t} + v \hat{C}_t + w(1 - v)\hat{E}R_t + (1 - v)\hat{C}^*_t + \hat{g}_{H,t}, \]  

(20)

\[ \hat{Y}_{N,t} = \hat{C}_t - w(1 - \gamma)\hat{P}_{NT,t} + \hat{g}_{N,t}, \]  

(21)

\[ \hat{C}_t = \frac{1}{\rho} \hat{E}R_t + \hat{C}^*_t, \]  

(22)

\[ \hat{E}R_t = v \hat{P}_{FH,t} - \gamma \hat{P}_{NT,t} + \gamma^* \hat{P}_{NT,t^*}, \]  

(23)

\[ \Delta \hat{P}_{NT,t} = \pi_{N,t} - \pi_{H,t} - (1 - v)\Delta \hat{P}_{FH,t} \]  

(24)

Moreover, from the price index relation (1a) we note that:

\[ \hat{P}_{HT,t} = -(1 - v)\hat{P}_{FH,t} \]  

(24a)

The Phillips curve relations in the two sectors are presented by equations (18) and (19), where \( k_L = \frac{(1 - \alpha_i)(1 - \sigma_i)}{\alpha_i(1 + \sigma_i)} \) is the constant that measures the response of the sectoral inflation rates to variations in real marginal costs. The characterization of real marginal costs in the open economy setting differs from that of the closed economy due to the gap between production and consumption as well as to the impact of relative prices, which reflect the distinction between domestic and consumer prices. An improvement in the terms of trade (a decrease in \( \hat{P}_{FH} \)) or a positive productivity shock result in a fall in marginal costs in the traded sector. The marginal costs in the non-traded sector are independent of direct changes in the terms of trade. However, the sectoral marginal costs are linked through the relative prices of non-traded goods. This impact is opposite in sign and symmetric in magnitude. Producers’ pricing decisions are forward-looking due to price stickiness. As a result, the Phillips curve takes the expectation-augmented form. Equations (20) and (21) describe the aggregate demand for domestic goods in the two sectors. We consider \( \hat{C}^*_t \) as a term that cannot be affected by dynamics in the home country. This variable is exogenous from the small open economy perspective. Relation (22) is the log-linearized optimal risk-sharing condition. It describes variations in domestic consumption depending on fluctuations in the real exchange rate and consumption abroad. Equation (23), which is derived from (12), summarizes the determinants of the real exchange rate. Again, the relative price of non-traded goods in the foreign country is treated as exogenous. This equation illustrates the implication of the multisectoral economic structure. In particular, changes in the terms of trade do not necessarily imply a corresponding adjustment of the exchange rate, due to the impact of the relative prices of non-traded goods at home and abroad.
Finally, expression (24), which is in fact an identity, is obtained from the definitions of non-traded and traded goods inflation and describes the evolution of the price indexes for both sectors. The equation that characterizes traded goods inflation is presented in the next subsection.

### 3.1.3 Domestic Inflation, CPI Inflation, and Some Aggregation Results

In this subsection we present several useful definitions and identities which will be used in the subsequent analysis. Log-linearization of price indexes (1) and (1a) yields:

$$
\hat{P}_t = \gamma \hat{P}_{N,t} + (1-\gamma) \hat{P}_{T,t} \\
\hat{P}_{T,t} = \nu \hat{P}_{H,t} + (1-\nu) \hat{P}_{F,t}
$$

Applying the definition of inflation $\pi_t = \ln \left( \frac{P_t}{P_{t-1}} \right) = \hat{P}_t - \hat{P}_{t-1}$ we obtain the expressions for CPI inflation and traded inflation:

$$
\pi_t = \gamma \pi_{N,t} + (1-\gamma) \pi_{T,t} \\
\pi_{T,t} = \nu \pi_{H,t} + (1-\nu) \pi_{F,t}
$$

Moreover, the definition of the terms of trade implies that $\pi_{F,t} = \Delta \hat{P}_{FH,t} + \pi_{H,t}$. The combination of the equations presented above results in the following relationship between CPI and domestic inflation:

$$
\pi_t = \pi_t^D + (1-\gamma)(1-\nu)\Delta \hat{P}_{FH,t}
$$

(25)

where domestic inflation equals:

$$
\pi_t^D = \gamma \pi_{N,t} + (1-\gamma) \pi_{H,t}.
$$

(25a)

Total output is given by:

$$
P_t Y_t = P_{N,t} Y_{N,t} + P_{H,t} Y_{H,t}
$$

(26)

Log-linearization of equation (26) yields:

$$
\hat{Y}_t = \gamma \hat{Y}_{N,t} + (1-\gamma) \hat{Y}_{H,t} - (1-\gamma)(1-\nu) \hat{P}_{FH,t}
$$

(27)

This relation implies that in an open multisectoral economy, aggregate output is not only the weighted average of the sectoral outputs, but also a function of relative prices.

Moreover, the evolution of the nominal exchange rate is derived from the definition of the real exchange rate and takes the form:

$$
\overline{ER}_t - \overline{ER}_{t-1} = \hat{S}_t - \hat{S}_{t-1} + \pi_t^* - \pi_t
$$

where $\hat{S}_t$ is the nominal exchange rate and $\pi_t^*$ is CPI inflation for the foreign country. We assume that the monetary authority abroad is implementing an inflation-targeting policy and thus $\pi_t^* = 0$. Such an assumption is common in the small open economy literature (Gali and Monacelli, 2005).
4. The Monetary Policy Problem and Welfare

This section will present the formulation of the monetary policy strategy and an analysis of the competing objectives of the central bank. We will see that the model specification implies deviations of the optimal monetary policy from complete price stabilization. Specifically, we present a formal welfare analysis and derive the objective function of the central bank based on a second-order approximation of both the household’s utility and the structural equilibrium conditions (18–24). Optimal monetary strategy involves maximization of the quadratic social welfare function (minimization of the loss function) subject to linear constraints. Monetary policy is able to achieve the best outcome from the welfare perspective by implementing the optimal plan. In this analysis we focus on optimal targeting rules, which are strongly advocated by Svensson and Woodford.

4.1 The Objective Function of the Central Bank for an Open Economy with Multiple Domestic Sectors

In order to obtain the analytical expression for welfare in a purely quadratic form, we apply the linear-quadratic solution methods described in Woodford (2003) and Benigno and Woodford (2005). This approach is based on the idea presented in Sutherland (2002) to explore the dynamic characteristics of the model and thus to account for the impact of the second moments of the variables on their levels. The derivation of the objective function of the central bank is presented in the Mathematical Appendix. We show that the utility function of the representative household can be approximated by the following expression:

\[ W_{t^o} = U_C \bar{C}E_{t^o} \sum_{t=t^o}^{\infty} \beta^{t-t^o} \times \]

\[ \left[ \hat{C}_t - (\pi_N)^{-1}(1 - \gamma)\hat{Y}_{N,t} + \frac{1}{2}(1 - \rho)\hat{C}_t^2 \right] \]

\[ -\frac{1}{2}(\pi_N)^{-1}(1 - \eta)\hat{Y}_{N,t}^2 - \frac{1}{2}(\pi_H)^{-1}(1 - \gamma)(1 + \eta)\hat{Y}_{H,t}^2 \]

\[ + (\pi_N)^{-1}2\eta\hat{A}_{N,t}\hat{Y}_{N,t} + (\pi_H)^{-1}(1 - \gamma)\hat{A}_{H,t}\hat{Y}_{H,t} \]

\[ -\frac{1}{2}\gamma\hat{\sigma}_{N,H}^2 - \frac{1}{2}(1 - \gamma)\hat{\sigma}_{H,N}^2 - t.i.p + \beta^2 \]

We eliminate the linear terms in the objective function by using a second-order approximation of the equilibrium structural equations (18–24). As a result, we obtain an objective function that is purely quadratic. The expression takes the following form:

\[ L_{t^o} = U_C \bar{C}E_{t^o} \sum_{t=t^o}^{\infty} \beta^{t-t^o} \times \]

\[ \left[ \frac{1}{2}W_{Y_N}(\hat{Y}_{N,t} - \hat{Y}_{N,t}^T)^2 + \frac{1}{2}W_{Y_H}(\hat{Y}_{H,t} - \hat{Y}_{H,t}^T)^2 + \frac{1}{2}W_{E_R}(\hat{E}_{R,t} - \hat{E}_{R,t}^T)^2 \right] + t.i.p, \]

\[ + W_{E_R}(\hat{E}_{R,t} - \hat{E}_{R,t}^T)(\hat{P}_{N,H} - \hat{P}_{N,H}^T) + \frac{1}{2}W_{\pi_N}(\pi_{N,t})^2 + \frac{1}{2}W_{\pi_H}(\pi_{H,t})^2 \]

where \( \hat{Y}_{N,t}^T, \hat{Y}_{H,t}^T, \hat{E}_{R,t}^T, \) and \( \hat{P}_{N,H}^T \) are welfare-relevant target variables, which are functions of stochastic shocks and, in general, may not be identical to the flexible price allocations.

Equation (29) implies that the social welfare of the two-sector small open economy is affected by deviations in the sectoral inflation rates, output gaps, and relative prices from their target values.

In fact, the objective function reflects the impact of various economic distortions on social welfare and illustrates their relative contributions to the loss. First of all, price rigidities and monopolistic distortions...
tions in both sectors, which may not be fully offset by production subsidies, result in economic inefficiencies and introduce a role for inflation and output gap stabilization. The cross-output variable \((\hat{Y}_{N,t} - \hat{Y}_{NT,t})^T(\hat{Y}_{H,t} - \hat{Y}_{HT,t})\) describes the impact of co-movement in the sectoral output gaps on social welfare. When the weight in the objective function associated with the interaction term is positive, the sectoral asymmetries might be welfare improving. When this weight is negative, co-movement of the sectoral outputs reduces welfare losses. In general, the weights next to each of the quadratic terms are represented by complicated functions of the structural parameters of the model (details are presented in the appendix).

Furthermore, when price rigidities are present in both sectors and domestic shocks are imperfectly correlated, price changes are not synchronized following a shock. This results in inefficient output dispersion between sectors and introduces a role for relative prices into the monetary policy design problem. In this case, not only do the levels of inflation in both sectors matter for welfare, but so does the deviation of the relative price from its target level. The open economy formulation brings an additional, cross-country, dimension into the problem described above. Specifically, nominal rigidities may prevent prices in both countries from adjusting efficiently after exchange rate movements. In other words, the so-called relative price channel can fail to function accurately; this may result in welfare gains from exchange rate stabilization. On the other hand, in an open economy the policymaker can manipulate the terms of trade in order to increase expected consumption and decrease the expected disutility of production, i.e., to improve welfare. Those incentives are called the terms of trade externality and were analyzed by Benigno and Benigno (2006). Therefore, the weight next to the exchange rate term in the loss function balances the stability objective determined by the economic distortions (nominal rigidities) with the incentive of creating additional volatility in excess of the fundamental shocks. The cross-factor \((\hat{E}_{ER,t} - \hat{E}_{ER,T})^T(\hat{P}_{NT,t} - \hat{P}_{NT,T})\) represents another "international dimension" term, which appears due to the fact that the relative price of non-traded to traded goods partially drives the evolution of the real exchange rate. This term, therefore, describes the additional welfare effects that originate from the correlation between the two relative prices.

Equation (29) indicates that the loss function derived for our model specification is not identical to the one of the closed economy or to the loss function obtained under the assumption \(\rho = \theta = \omega = 1\). The general welfare representation, however, embodies these two special cases, which coincide in terms of policy objectives and imply that \(W_{YNYH} = 0\) and \(W_{ER} = W_{PNT} = W_{ERPNT} = 0\).

The presence of open economy terms is not the only implication of the exposure to external factors that can be observed in the objective function. The relative weights on the sectoral inflation rates and output gaps are not only affected by the structural asymmetries, like in the case of the closed economy, but also display the incentives that arise under openness to trade of one of the domestic sectors. Specifically, in an open economy, the weights in the objective function imply relatively higher stabilization of the non-traded sector compared to the traded sector variables. Figures 1 and 2 present the weights on inflation rates and output gaps as functions of the non-traded sector size derived for the closed and open economies, respectively. The weights are computed under the baseline parameterization.
Two important results can be highlighted when analyzing the figures presented above. Firstly, graphs 1 and 2 indicate that both sectors are more volatile under the optimal policy when the economy is open (the weights are lower for all values of \( \gamma \)). Secondly, the decomposition of weights between sectors changes depending on whether the economy is subject to external factors. In particular, figure 1 indicates that the weights derived for the closed economy model are symmetric and determined mainly by the parameter \( \gamma \). The equal size of both sectors (\( \gamma = 0.5 \)) implies their equal contribution to the loss function. On the contrary, figure 2 demonstrates that in the open economy the stabilization "bias" is shifted toward the non-traded sector. In other words, the sector that is open to trade is allowed to adjust more at the optimum compared to the sector that produces goods only for internal consumption. Such a result is driven by incentives to explore the terms of trade externality in a welfare-improving manner combined with the monopolistic competition in the traded goods sector in countries H and F (measured by the parameter \( \theta \)). Specifically, domestic households can benefit from volatility in the traded sector by varying the consumption and output of home goods. The possibility to substitute for foreign goods in the consumption basket enables households to "divert" a part of production abroad and thus to lower the costs of the home-goods inflation and reduce the economic inefficiencies. Therefore, the terms of trade externality influences the weights of both the relative price terms and the domestic variables in the loss function. This effect is increasing in the elasticity of substitution between home and foreign traded goods \( \theta \).

### 4.1.1 The Relevance of the Welfare-Based Objective Function to the Current Practice of Central Banks

The loss functions widely assumed in the literature on monetary policy are typically represented by a quadratic expression that includes a weighted combination of inflation (CPI or domestic) and total output gap terms. Analyzing the micro-founded welfare objective function (29) we can see that it differs from the ad hoc forms in two important respects. First of all, it includes an open economy term and, therefore, prescribes a certain degree of exchange rate management. Secondly, it reflects the multisectoral economic structure and differentiates between sector-specific inflation rates and output gaps. Thus, the loss function derived on the basis of the economic fundamentals appears to be significantly more complex than the ad hoc policy objectives.
It is important to clarify why the objective function (29) does not explicitly display an important practical feature of current monetary policy conduct. Specifically, the majority of the central banks which have adopted inflation targeting as an operational framework have specified their monetary policy objective in terms of CPI inflation. Equation (29) indicates that the welfare loss of a small open economy depends on the appropriate measure of domestic inflation rates and is not explicitly affected by import price inflation. On the other hand, equation (25) illustrates the role of relative prices in movements of the foreign inflation rate. Thus, the welfare-based objective function indirectly includes all components of CPI inflation (except the lagged relative prices) but with the optimal weights.

At the same time it is possible to describe the conditions under which the explicit \( \pi_{F,t} \) term can appear in the loss function. In the most general case, the loss function captures the distortions present in the domestic economy as well as the interrelations with the rest of the world. In particular, when countries are big enough, economic developments in the neighboring economy can affect domestic welfare and vice versa. The set of structural constraints for each country includes, in this case, both the domestic and foreign equations. Since the quadratic welfare objective function is derived from the approximation of the welfare function and the structural equations, the interaction between economies can bring foreign variables into the loss function of the domestic economy with country-specific weights. Such a framework is presented in Benigno and Benigno (2006), where they consider a two-country model with countries of comparable size. This paper demonstrates that despite the non-zero weight on foreign inflation in the loss function, the optimal targeting rules suggest a certain role for CPI inflation only in the case of cooperation between countries. Such a result can be explained by the fact that under the Nash regime (the non-cooperative case) the objective function is minimized only with respect to domestic variables, and the strategy of the other policymaker and the sequence of the foreign inflation rate are taken as given. In other words, the monetary authority does not care about the impact of domestic policy on the other country. In the cooperative case, the effects of the actions in both countries are internalized and the social planner optimizes with respect to all endogenous variables (domestic and foreign). As a result, the optimal targeting rule contains the proper measure of world inflation, which brings a role for CPI targeting.

Coming back to the model presented in this paper, the small open economy framework and, more specifically, the limiting case \((n \to 0)\) imply that the domestic economy cannot influence the foreign country because of its small size, and the rest of the world can be treated as a closed economy. In this sense, countries are not directly interrelated in terms of consumption and production. The set of structural constraints for country H contains only the domestic equations and the foreign variables are treated as exogenous from the small open economy perspective. The implications of the foreign variables as well as other structural shocks can be observed in the targets, the deviations from which the central bank is trying to minimize. All other effects of the foreign dynamics are out of the control of the domestic policymaker and can be interpreted as unavoidable losses or as terms that are independent of policy.
4.2 The Optimal Monetary Policy Rules

In order to obtain the optimal targeting policy rules, we minimize the objective function (29) subject to the set of constraints, which are given by:

\[
\pi_{H,t} = k_H \left[ \eta (\bar{Y}_{H,t} - \bar{Y}_{H,t}^T) + \frac{1}{\nu} (E_{R,t} - \bar{E}_{R,t}^T) + \gamma \left( \frac{P_{NT,t} - \bar{P}_{NT,t}}{\nu} \right) + u_t^H \right] + \beta E_t \pi_{H,t+1}, \tag{30}
\]

\[
\pi_{N,t} = k_N \left[ \eta (\bar{Y}_{N,t} - \bar{Y}_{N,t}^T) + (E_{R,t} - \bar{E}_{R,t}^T) - (1 - \gamma) (P_{NT,t} - \bar{P}_{NT,t}) + u_t^N \right] + \beta E_t \pi_{N,t+1}, \tag{31}
\]

\[
(\bar{Y}_{H,t} - \bar{Y}_{H,t}^T) = \frac{l + 1}{\rho \nu} (E_{R,t} - \bar{E}_{R,t}^T) + \gamma \left[ \frac{l + 1 + \nu^2 (\rho \omega - 1)}{\nu} \right] (P_{NT,t} - \bar{P}_{NT,t}) + \chi_t^H, \tag{32}
\]

\[
(\bar{Y}_{N,t} - \bar{Y}_{N,t}^T) = \frac{1}{\rho} (E_{R,t} - \bar{E}_{R,t}^T) - \omega (1 - \gamma) (P_{NT,t} - \bar{P}_{NT,t}) + \chi_t^N, \tag{33}
\]

\[
(1 - \nu) \Delta (E_{R,t} - \bar{E}_{R,t}^T) = \nu (\pi_{N,t} - \pi_{H,t}) - (\nu + \gamma (1 - \nu)) \Delta (P_{NT,t} - \bar{P}_{NT,t}) + \varepsilon_t. \tag{34}
\]

where \( l = (\rho \theta - 1)(1 - \nu)(1 + \nu) \), and the terms \( u_t^H, u_t^N, \chi_t^H, \chi_t^N, \varepsilon_t \) are functions of exogenous shocks and arise when the target levels of variables and flexible price allocations diverge. The conditions (30)–(34) are obtained by combining the log-linearized equilibrium conditions (18)–(24) and expressing the relations in terms of gap variables. We assume that the central bank can commit to the policy that maximizes welfare and consider the timeless perspective approach described in Woodford (2003). The timeless perspective optimal policy assigns the particular value to the commitment to expectations prior to period 0. The constraints on the initial conditions result in the time-invariant first-order conditions and thus optimal policy. Therefore, the time inconsistency problem is eliminated. Following such a strategy, the policymaker chooses the path for endogenous variables \( \pi_{H,t}, \pi_{N,t}, \bar{Y}_{H,t}, \bar{Y}_{N,t}, E_{R,t}, \bar{P}_{NT,t} \) subject to constraints (30)–(34) and given the initial conditions on \( \pi_{H0}, \pi_{N0}, \bar{Y}_{H0}, \bar{Y}_{N0} \). The Lagrange multipliers associated with the set of constraints are \( \lambda_{1,t} - \lambda_{5,t} \) respectively. In addition, before the optimization we divided equation (30) by \( k_H \), equation (31) by \( k_N \), and equation (34) by \( \nu \). The first-order conditions to the problem are given by:

\[
W_{\pi_H} k_H \pi_{H,t} = \lambda_{1,t} - \lambda_{1,t-1} + \lambda_{5,t} k_H, \tag{35}
\]

\[
W_{\pi_N} k_N \pi_{N,t} = \lambda_{2,t} - \lambda_{2,t-1} - \lambda_{5,t} k_N, \tag{36}
\]

\[
W_{\pi_{HH}} (\bar{Y}_{H,t} - \bar{Y}_{H,t}^T) + W_{\pi_{HN}} (\bar{Y}_{N,t} - \bar{Y}_{N,t}^T) = \lambda_{3,t} - \eta \lambda_{1,t}, \tag{37}
\]

\[
W_{\pi_{NN}} (\bar{Y}_{N,t} - \bar{Y}_{N,t}^T) = \lambda_{4,t} - \eta \lambda_{2,t}, \tag{38}
\]

\[
W_{ER} (E_{R,t} - \bar{E}_{R,t}^T) + W_{ER,PN_T} (\bar{P}_{NT,t} - \bar{P}_{NT,t}^T) = \left( \frac{l + 1}{\rho \nu} \lambda_{1,t} - \frac{1 - \nu^2 (\rho \omega - 1)}{\nu} \lambda_{3,t} + \frac{1 - \nu^2 (\rho \omega - 1)}{\nu} (\lambda_{5,t} - \beta \lambda_{5,t+1}) \right), \tag{39}
\]

\[
W_{P_{NT}} (\bar{P}_{NT,t} - \bar{P}_{NT,t}^T) + W_{ER,PN_T} (E_{R,t} - \bar{E}_{R,t}^T) = \left( \frac{-\gamma}{\nu} \lambda_{1,t} + (1 - \gamma) \lambda_{2,t} - \frac{\gamma (l + 1 + \nu^2 (\rho \omega - 1))}{\rho \nu} \lambda_{3,t} + \omega (1 - \gamma) \lambda_{4,t} + \left( 1 + \frac{1 - \nu^2 (\rho \omega - 1)}{\nu} \right) (\lambda_{5,t} - \beta \lambda_{5,t+1}) \right). \tag{40}
\]

Combining equations (35)–(40) we can eliminate the Lagrange multipliers and express the optimal policy rule in the following general form:

\[
A^0 \Delta \bar{X}_t + A^1 \Delta \bar{X}_{t-1} + A^2 \Delta \bar{X}_{t+1} = 0 \tag{41}
\]

where \( A^0, A^1, A^2 \) are the matrices of parameters, \( \Delta \bar{X}_t = \bar{X}_t - \bar{X}_{t-1} \), and \( \bar{X}_t = \bar{X}_t - \bar{X}_t^T \), i.e., \( \bar{X}_t \) denotes the vector of the endogenous variables \( (\pi_{H,t}, \pi_{N,t}, \bar{Y}_{H,t}, \bar{Y}_{N,t}, E_{R,t}, \bar{P}_{NT,t}) \) in deviations from their target values.
Therefore, the optimal policy rule is represented by a fairly complicated expression that prescribes the response to deviations in the sectoral inflation rates and output gaps as well as to fluctuations in relative prices. The reaction function (41) includes both backward and forward-looking endogenous variables. The matrices of the parameters $A_i$ which describe the optimal magnitude of the response, depend on the optimal weights and the structural parameters of the model.

For comparison, the optimal policy rule derived with the use of the similar methodology for the one-sector open economy model takes the general form: $A^0 \Delta \bar{X}_t = 0$. Therefore, the multi-sectoral model specification brings in more complex dynamics of variables under the optimal policy. Specifically, rule (41) is more persistent, i.e., it prescribes the response to the first and the second lag of the endogenous variables. Moreover, the rule contains forward-looking components, since $A^2 \neq 0$. The characteristics of the policy rule mentioned above are determined by the persistent structure of one of the model equations (34), which describes the evolution of the sector-specific inflation rates and the two types of relative prices.

4.2.1 Policy Trade-Offs

The welfare function (29) indicates that the monetary authority is confronted with several policy objectives. In particular, the central bank has to control the sector-specific inflation rates and output gaps, as well as relative prices. In order to study the optimal plan, it is important to investigate whether the policy goals can be simultaneously attained or the central bank has to decide how to balance them appropriately. Where the objectives do not conflict with each other, the central bank can achieve the first best allocation and completely eliminate the loss. In this section we describe the policy trade-offs that arise in a generalized model of a two-sector small open economy.

We analyze equation (24) expressed in terms of the welfare-relevant gap variables:

$$
(1 - v)\Delta (\bar{E}_R t - \bar{E}_R^T_t) = v(\pi_{NT,t} - \pi_{H,t}) - (v + \gamma(1 - v))\Delta (\bar{P}_{NT,t} - \bar{P}_{NT}^T) + \varepsilon_t
$$

(42)

The gaps depend on the target levels of the variables, which in turn are functions of the shocks and parameters and vary over time. Equation (42) indicates that it is not possible to stabilize inflation rates in each sector and to eliminate the gaps between relative prices and their target values at the same time. In fact, relative prices act as endogenous shocks that do not allow the same policy to attain zero inflation in both sectors. For example, under a productivity shock in the non-traded goods sector (figure 4), the optimal policy implies depreciation of the nominal exchange rate. Complete stability of non-traded inflation would require an even larger increase in the exchange rate. This, however, would result in a further worsening of the terms of trade and a greater rise in home-goods inflation. A similar trade-off exists under fiscal and mark-up shocks. Moreover, the impulse-responses indicate that the magnitude of the response differs across sector-specific variables. The different sensitivity of the domestic sectors to shocks is determined not only by structural asymmetries such as sector size, elasticity of substitution, and the level of nominal rigidities, but also by the openness to trade of one of the domestic sectors. Therefore, the optimal policy cannot comply with all the sector-specific stabilization objectives simultaneously. Woodford (2003) illustrates that a corresponding trade-off also exists in the closed economy model ($\gamma=1$) if the target rate of the relative price (the natural rate) is not constant.

Furthermore, we address the question of whether complete stability of the aggregate variables is attainable under the given economic structure. We present the Phillips curve relations in terms of gap variables and use the definition of domestic inflation. Moreover, in this analysis we assume for simplicity that the target variables and flexible price allocations coincide and the degree of nominal rigidities is equal across sectors. We combine the constraints (30)–(33) and apply the definition of domestic inflation (25a). As a
result, the following relationship arises:

$$\pi_t^D = k \left[ (\eta + \rho) \left( \gamma (\tilde{Y}_{N,t} - \tilde{Y}_{N,t}^{flex}) + (1 - \gamma)(\tilde{Y}_{H,t} - \tilde{Y}_{H,t}^{flex}) \right) \left( \frac{(1 - \gamma)}{\rho \theta - 1} \beta \pi_{t+1}^D \right) \right] + \beta E_t \pi_{t+1}^D \quad (43)$$

where $l = (\rho \theta - 1)(1 - v)(1 + v), \tilde{l} = l - (\rho \omega - 1)(1 - v)v$, and the flexible price allocations of the variables are functions of the exogenous shocks $\tilde{A}_{H,t}, \tilde{A}_{N,t}, \tilde{P}_{NT,t}^{flex}; C_t^t$. Moreover, we make use of equation (27) and provide the alternative domestic Phillips curve relation in order to analyze the impact of the aggregate output gap instead of the differentiation between the sectoral variables:

$$\pi_t^D = k \left[ (\eta + \rho) \left( \gamma (\tilde{Y}_{t} - \tilde{Y}_{t}^{flex}) + (1 - \gamma)(1 - v)(\tilde{P}_{F,H,t} - \tilde{P}_{F,H,t}^{flex}) \right) \left( \frac{(1 - \gamma)}{\rho \theta - 1} \beta \pi_{t+1}^D \right) \right] + \beta E_t \pi_{t+1}^D \quad (44)$$

We present two special cases of our more general analysis in order to describe the role of relative prices in generating the policy trade-offs. Firstly, we consider a two-sector closed-economy setting, i.e., $v = 1, \gamma > 0$. In such a situation $l = \tilde{l} = 0$. Equations (43) and (44) illustrate that the sectoral Phillips curves reduce to the classical aggregate relation, which, at the same time, describes the dynamics for the one-sector closed economy. Therefore, there is no conflict between inflation and output gap stabilization, and optimal monetary policy is able to implement the first best, i.e., flexible price allocation. This result has been shown by Woodford (2003).

Secondly, we assume the special case of unitary elasticity of substitution and a unitary coefficient of relative risk aversion, i.e., the balanced trade model specification as in Liu and Pappa (2005). Again we have $l = \tilde{l} = 0$. Thus the exchange rate and relative prices vanish from the Phillips curve relations (43) and (44). Moreover, the assumption $\rho = \theta = \omega = 1$ implies that the exchange rate does not characterize a welfare-relevant policy objective. In this situation, the terms of trade act as an endogenous "cost-push shock," which generates tension between domestic inflation and the output gap. In fact, such a trade-off can be generated in closed economy models in the presence of mark-up shocks or adjustment costs (Benigno and Woodford, 2005; Erceg and Levin, 2006).

Finally, we consider our two-sector model under general preferences. The Phillips curve (43) illustrates that the stabilization of domestic inflation and outputs in both sectors does not involve equivalent policies, due to the presence of relative prices. Moreover, equation (44) indicates that there is tension between domestic inflation and exchange rate stability in addition to the trade-off between domestic inflation and aggregate output gap variability. Therefore, unless preferences are specified in the general form, the conflict between managing domestic inflation and the real exchange rate ceases to exist.

The fairly complex economic structure and general model specification determine the non-trivial task facing policymakers, i.e., the search for the second-best optimal policy given that the flexible price efficient allocation of resources cannot be replicated. The optimal reaction function (41), in fact, represents such a second-best solution. A similar result is obtained in the one-sector open-economy model analyzed by De Paoli (2006). In our case, however, the definition of the real exchange rate implies a distinction between the two types of relative prices and enables us to characterize the dynamics and impact of each variable separately. Moreover, the multiple sectors imply an additional policy challenge, i.e., the proper management of the "between-sector" terms.
5. Impulse-Response Functions

In this section we examine the impulse-responses of key macroeconomic variables to exogenous shocks. Specifically, we compare the numerical results under the optimal plan with the outcomes achieved under the basic simple rules common in the literature, such as domestic inflation targeting (DIT), consumer price index inflation targeting (CPIT), and an exchange rate peg (PEG). We consider four types of shocks, i.e., productivity, foreign, fiscal, and mark-up shocks. For the numerical exercise we assume the coefficient of relative risk aversion $\rho = 3$ and the elasticity of substitution between differentiated goods $\sigma = 10$ as in Benigno and Benigno (2006). Following Rotenberg and Woodford (1997) we set $\beta = 0.99$ and $\eta = 0.47$. The elasticity of substitution between traded home and foreign goods $\theta$ is assumed to be equal to 1.5 and the parameter that measures the substitution between non-traded and traded goods $\omega$ is set to 0.5. The level of price rigidities $\alpha = 0.66$, implying that the average length of price contracts is equal to 3 quarters. These assumptions are common in the open economy literature. In our benchmark specification we consider an equal level of price rigidities across sectors. Moreover, the share of non-traded goods in the consumption basket $\gamma$ is set to 0.5. The degree of openness $v = 0.6$, implying a 40% import share. Finally, the steady state mark-up in the traded sector $\mu_H$ is set to the value $1/v$ as in Liu and Pappa (2005) and De Paoli (2006) in order to guarantee the optimal subsidy policy. In addition, the equal size of both domestic sectors implies that $\mu_H = \mu_N$. In this paper we assume that shocks are uncorrelated and have equal variance $\sigma^2 = 0.0001$.

Figure 3 represents the impulse-responses to a positive productivity shock in the traded sector, $\hat{A}_H$. All regimes (except PEG) imply a reaction of the monetary authority that induces a depreciation of the nominal exchange rate. Such dynamics, together with a fall in the price of home goods, worsen the terms of trade and thus result in a real depreciation. The increase in the exchange rate is the largest under DIT, because in this case the central bank stabilizes inflation more aggressively. In fact, higher home-goods inflation stability is traded for some additional exchange rate volatility. CPI inflation rises under DIT and the optimal plan. Here two effects are at work: the impact of the nominal exchange rate and the adjustment of the sectoral inflation rates after the productivity shock. Specifically, the increase in the exchange rate and prices in the non-traded sector dominate the fall in home-goods inflation, and the overall impact on CPI inflation is positive. Under PEG, the nominal exchange rate is stable and the effect of the productivity shock on CPI inflation is determined by the fall in inflation in the home-goods sector.

Domestic output increases due to the real exchange rate depreciation. Domestic goods become relatively cheaper than foreign goods. However, the increase in output is not large enough to boost production above its target level and the total impact on the output gap is negative. The expenditure switching effect is the most pronounced under the DIT regime, which implies no control over the exchange rate and thus allows for greater real depreciation. As a result, the output response is the largest. On the contrary, under PEG and CPIT the expenditure switching effect is minimized and the output gap falls by more compared to the other regimes.

The negative response of home-goods inflation under all the regimes is determined by the direct impact of the productivity shock, which lowers the marginal costs in this sector. However, the marginal costs in the non-tradable sector increase. Specifically, non-traded output increases and the relative price of non-traded to traded goods $\tilde{P}_{NT}$ falls under DIT and the optimal plan, due to nominal depreciation. As a result, non-traded inflation rises.

Figure 4 presents the impulse-response to a productivity shock in the non-traded sector, $\hat{A}_N$. The dynamics of the variables can be described in a similar fashion. The shock lowers the marginal costs in the non-traded sector and inflation in this sector falls. As in the previous case, the reaction of the monetary
authority causes depreciation of the nominal exchange rate. Both the fall in the price of non-traded goods and the nominal depreciation, which worsens the terms of trade, result in real depreciation. Inflation in the home-goods sector rises due to the increase in the terms of trade. It is important to note that non-traded inflation is stabilized to a greater extent under the optimal plan compared to the alternative simple rules. The reason for such a policy reaction is that the optimal welfare function assigns the greatest weight to stabilization of non-traded inflation. At the same time, the productivity shock $\hat{A}_N$ directly affects the price change in this sector and, hence, induces greater dynamics of this variable. In order to prevent large swings in non-traded inflation, the central bank allows greater adjustments in relative prices and output. In addition, the response of relative prices ($\widehat{P}_{NT}$ and $\widehat{ER}$) is almost two times stronger than the responses of these variables following the productivity shock $\hat{A}_H$. Again, the reason is that instability of non-traded inflation has larger negative welfare consequences than changes in home-goods inflation.

The output reaction is positive in both sectors due to the large expenditure switching effect under DIT and the optimal plan. Unlike the negative response of the output gap following the productivity shock in the home-goods sector, the $\hat{A}_N$ shock results in an increase of output above its target level due to the more expansionary policy.

Figure 5 presents the responses of domestic variables to the innovation in foreign consumption, $\hat{C}^*$. We can observe that the DIT regime is similar to the optimal plan in terms of the direction and magnitude of the response. The foreign consumption shock raises domestic consumption through the risk-sharing condition. This, in turn, may induce an increase in domestic output. At the same time, the nominal and real exchange rates appreciate and the terms of trade fall. Domestic goods become relatively less competitive and demand shifts to foreign goods. The net effect on home output is negative under DIT and the optimal plan. The exchange rate appreciation and the output fall are larger under the DIT regime. In this case, the effect of the shock on aggregate domestic production exactly matches the impact of the disturbance on the target level of output and the response of the gap variable is zero. CPI inflation falls due to the exchange rate appreciation. At the same time the sectoral inflation rates show just a slight response to the shock. The impact of the shock on the macro-variables is qualitatively different under the CPIT and PEG regimes. Specifically, the monetary authority stabilizes relative prices and the real appreciation is small. The expenditure switching effect is dominated by the positive impact of the shock on domestic consumption and demand. As a result, the outputs in both sectors as well as the output gap show a significant increase. Such a boost in production increases marginal costs, and inflation in both sectors rises.

Figure 6 presents the impulse-responses to a shock to foreign relative prices, $\hat{P}_{NT}^*$. An increase in the relative price of non-traded to traded goods abroad could be caused by a decrease in the price of foreign goods $\hat{P}_T^*$ following the productivity shock in sector $F^*$. Again, the DIT regime almost perfectly replicates the optimal response. The reaction of the central bank results in a small nominal depreciation. The change in relative prices, however, is significant. The terms of trade fall sharply due to a decrease in the domestic currency price of foreign goods. The relative price of non-traded to traded goods increases. Domestic households substitute for cheaper goods in the consumption basket and demand in the home-goods production sector falls. Non-traded output remains almost unaffected due to the low elasticity of substitution between goods $N$ and $H$. CPI inflation falls following the decrease of the terms of trade, whereas the responses of the sectoral inflation rates are quantitatively small.

The policy reaction following the $\hat{P}_{NT}^*$ shock displays a sharp contrast between the responses under the CPIT and PEG regimes, whereas under the other types of shocks these two regimes induce very similar changes in economic activity. Specifically, under the CPIT regime the central bank prevents large movements in the terms of trade at the expense of additional domestic inflation volatility. The policy implies a large nominal depreciation so as to mitigate the negative impact of foreign prices on the terms
of trade. The nominal depreciation under the stabilized CPI inflation results in real depreciation. This, in turn, increases domestic production and inflation in both sectors. On the contrary, the PEG regime induces a policy that is closer to the optimal plan and DIT. Where foreign and home goods are substitutes, the optimal response implies a greater nominal exchange rate stabilization in order to improve the terms of trade and divert production abroad by switching to consumption of foreign goods. Such a policy is welfare improving because it enables one to take advantage of the foreign productivity shock by reducing domestic marginal costs and the inefficient output dispersion associated with price rigidities.

Figure 7 shows the impulse responses to a mark-up shock in the home-goods sector, $\mu_H$. The optimal policy diverges from complete domestic inflation stabilization and the other alternative simple rules. The positive shock leads to a rise in home-goods inflation, which returns to its initial level after several periods of deflation, and a temporary fall in the output gap. The extent to which the shock affects output versus inflation depends on the weight that the central bank places on output gap variability in the loss function. Specifically, the optimal policy, unlike the alternative simple rules, implies a certain degree of output gap stability. Therefore, inflation is allowed to increase more and the output gap to fall less under the optimal plan. The response of the monetary authority to a mark-up shock implies depreciation of the exchange rate, an increase in the terms of trade, and a fall in the relative price of non-traded to traded goods. Domestic consumption rises in response to a shock. As a result, the outputs in both domestic sectors increase. The output gap, however, falls due to the fall in home-goods output below its target value.

The responses to a mark-up shock in the non-traded sector, $\mu_N$, are presented in Figure 8. Again, the central bank has to balance conflicting policy objectives – to absorb the upward pressure on inflation in the non-traded sector by a fall in the output gap. The exchange rate appreciates and consumption and output decrease under the optimal plan. The DIT regime implies a greater economic contraction and thus the largest fall in output and consumption. CPIT and PEG represent strongly suboptimal regimes because they induce excessive stabilization of relative prices and a higher response of non-traded inflation.

The comparative analysis of impulse-responses under the $\mu_H$ and $\mu_N$ shocks suggests that the optimal policy reacts more aggressively under the disturbance to a non-traded mark-up. Such a response reflects the decomposition of weights in the welfare objective function, which assigns higher weights to the non-traded sector variables. The optimal policy implies a greater economic contraction under the $\mu_N$ shock. The output gaps in both sectors and consumption fall in order to reduce the upward pressure on non-traded inflation, the variable which may induce the largest welfare losses. As a result, the allowed non-traded inflation volatility following the $\mu_N$ shock is more than two times smaller than the response of home-goods inflation after the $\mu_H$ shock. In addition, the decrease in the output gap in the home-goods sector absorbs the major part of the positive upward pressure on inflation. In other words, the aggregate output gap changes to a greater extent due to the adjustment of the traded sector output gap, which is allowed to be more volatile under the optimal plan.

Figures 9 and 10 illustrate the responses to fiscal shocks in the traded and non-traded sectors, respectively. Again, the optimal policy differs significantly from the simple policy rules. The rise in government spending $g_H$ increases home-goods output. The central bank, which aims at domestic inflation stabilization, offsets the upward pressure on home-goods inflation by a corresponding decrease in non-traded inflation. The response induces an initial appreciation of the exchange rate, a fall in the terms of trade, and a rise in the relative price of non-traded to traded goods. As a result, consumption and non-traded output decrease. The optimal plan, on the contrary, implies a somewhat expansionary policy. The exchange rate depreciates, implying an additional stimulus to output in both domestic sectors. Such a policy prevents the initial drop in consumption. The CPI and PEG regimes imply greater stability of relative prices. A slight fall in the terms of trade turns out to be sufficient for consumer price stabilization.
The government spending shock $\hat{\gamma}_N$ increases non-traded output and creates upward pressure on non-traded inflation. Therefore, unlike in the previous case, the optimal policy implies an economic contraction. The response of the central bank is the most aggressive compared to the alternative policy rules. The nominal exchange rate sharply appreciates and output in the traded sector and consumption decrease. The relative price of non-traded to traded goods increases because non-traded goods become relatively scarce and import prices fall. As a result, greater non-traded inflation stability is achieved at the expense of additional volatility of inflation and output in the traded sector, as well as a larger adjustment of relative prices.

The analysis of the numerical results suggests that the type of shock and the economic structure are important determinants of the comparative performance of optimal versus simple policy rules. Specifically, the responses under the optimal policy differ the most from the simple rules under fiscal and mark-up shocks. On the contrary, the DIT regime better approximates the optimal plan under foreign and productivity shocks. In addition, the optimal and PEG regimes come closer under a foreign relative price shock. Shocks of the same type but affecting different domestic sectors may induce qualitatively distinct economic responses due to the sector-specific weights in the optimal welfare function. In particular, the optimal policy is expansionary with respect to fiscal and mark-up shocks in the traded sector, whereas identical shocks in the non-traded sector call for an economic contraction.

The DIT regime induces a more expansionary policy under a traded-sector productivity shock, whereas the policy is less active following foreign shocks. Fiscal and mark-up disturbances result in an economic contraction under DIT. Under the CPI and PEG regimes, the policy is less aggressive in response to domestic productivity shocks and it becomes more expansionary under foreign shocks.

The study of the optimal policy problem presented in the previous sections provides a useful theoretical foundation for the design of monetary strategy and offers a rigorous benchmark for comparing the performance of alternative monetary regimes. At the same time, the prescriptions of the optimal policy given by expression (41) might be too difficult for the general public to interpret and too difficult to put into practice. Therefore, the analysis of the alternative policy rules, which deliver reasonable welfare results and at the same time are simple and transparent, and the optimal rule, which has normative implications, should interact in a complementary way in order to provide beneficial economic conclusions. In this section we enhance the analysis of the optimal policy with a discussion of the alternative simple rules and present their comparative performance. Specifically, we use Dynare software in order to compute so-called *optimal simple rules* (OSRs). As a result, we are able to analyze rules with a simple structure but with optimized coefficients.

We address two important issues. Firstly, we consider several types of alternative simple rules classified depending on the variables entering the rules and investigate the extent to which alternative monetary regimes are able to replicate the optimal solution. Secondly, we explore the implications of the alternative simple rules for macroeconomic volatility.

The welfare ranking is performed on the basis of the value of the loss, which is computed by taking the unconditional expectations of expression (29), i.e., the second-order approximation to the utility of the representative consumer, expressed as a fraction of the steady state consumption. As a result, we present the value of the loss in terms of the variances/covariances of the sector-specific inflation rates, output
gaps, and relative prices:
\[ V = \frac{\beta}{1 - \beta} \times \left[ \frac{1}{2} W_{Y_{N,v}} \text{var}(\tilde{Y}_{N,t}) + \frac{1}{2} W_{Y_{H,v}} \text{var}(\tilde{Y}_{H,t}) + W_{Y_{N,Y_{H}}} \text{covar}(\tilde{Y}_{N,t}, \tilde{Y}_{H,t}) + \frac{1}{2} W_{ER} \text{var}(\tilde{E}_{R,t}) + \frac{1}{2} W_{P_{N}} \text{var}(\tilde{P}_{NT,t}) + W_{ER,P_{NT} \text{covar}}(\tilde{E}_{R,t}\tilde{P}_{NT,t}) + \frac{1}{2} W_{\pi_{N}} \text{var}(\tilde{\pi}_{N,t}) + \frac{1}{2} W_{\pi_{H}} \text{var}(\tilde{\pi}_{H,t}) \right]. \] (45)

Table 1 reports the welfare losses associated with various types of OSRs. Specifically, we consider simple rules which include domestic variables only and rules that prescribe the response to both closed and opened economy terms. In addition, we would like to evaluate the benefits of targeting sector-specific inflation rates and outputs versus aggregate variables. This issue is practically important since central banks do not usually differentiate their policy response depending on the economic sector and consider aggregate variables, due to the problem of policy implementation and a lack of information. Moreover, we consider rules that include lagged domestic inflation, because the optimal reaction function (41) contains persistent components.

</table>

Table 1 indicates that the welfare losses under the OSRs are on average (except for the CPI and PEG regimes) 10-30% larger compared to the optimal rule. The DIT regime performs worse compared to the results obtained in the previous literature. In particular, in the special case of the open economy model presented in Gali and Monacelli (2005) and the framework with ad-hoc welfare objectives as in Soto (2004), the DIT regime represents or nearly replicates the first-best. In our case, however, the ranking of alternative regimes suggests that strict inflation targeting is suboptimal compared to policies that account for other policy objectives. Specifically, the DIT strategy is dominated by the rules that prescribe the response to deviations in the output gap. Moreover, the rules that account for sector-specific variations in outputs perform better compared to the case of targeting the aggregate variable. In particular, implementing rule 3 instead of rule 2 brings a 10.3% reduction in the welfare losses. At the same time, augmenting the rule that responds to domestic inflation and total output with an exchange rate term allows one to achieve a welfare result that is equivalent to the case of targeting the traded and non-traded output gaps separately. Furthermore, the inclusion of lagged domestic inflation in the policy rule further improves welfare, though to a lesser extent. Complete stabilization of the appropriately weighted average of the sectoral inflation rates (rule 6) produces better results than DIT. However, rule 6, which anyway responds merely to price changes, is dominated by the strategies that incorporate the output and exchange rate policy objectives. The CPI and PEG regimes represent the least attractive alternatives to the optimal rule from the welfare viewpoint. The poor performance of CPI targeting can be explained...
by the excess smoothness of relative prices which this regime entails. Over-stabilization of the terms of
trade prevents prices from adjusting efficiently in response to shocks and augments the negative impact
of nominal rigidities on welfare. This generates a significant deviation from the optimal policy. In
other words, CPI targeting represents too general a policy regime. It aggregates several welfare-relevant
variables (domestic inflation rates and relative prices), prescribing a suboptimal reaction to deviations in
these terms.

The values of the optimized coefficients $k_1, k_2, k_3, \text{ and } k_4$ displayed in table 1 provide information about
the relative magnitude of the policy response to deviations in key macroeconomic variables. Specifically,
the OSRs indicate that the policy should respond more aggressively to variations in the non-traded sec-
tor variables. The response to uctuations in the exchange rate is approximately $\frac{1}{2}$ of the response to
deviations in the output gap.

The important criterion for evaluating the performance of the simple rules is the level of macroeconomic
stability which they induce. Alternative regimes may generate comparable welfare results but, at the
same time, imply different volatility of the macroeconomic variables. This issue becomes particularly
important prior to entering the Eurozone, when the monetary authority has to fulfill specific and some-
times conflicting stabilization objectives. Table 2 presents the standard deviations of the key variables
under different OSRs relative to the standard deviations implied by the optimal policy.

</table>

Comparing the volatility under the alternative regimes we note that the rules that strictly target aggregate
variables naturally perform the worst in terms of stabilization of the particular economic sectors. Thus,
der under the DIT, CPI, and PEG regimes, the volatility of the sector-specific variables diverges the most
from the deviations implied by the optimal rule. In particular, both sectoral inflation rates are 45–12%
over-stabilized under the DIT regime. At the same time, the output gap in the home-goods sector is
almost 40% more volatile relative to its standard deviation under the optimal policy.
The comparison of DIT and the rule that targets the properly weighted domestic inflation index (rule 6) suggests that under the latter, non-traded inflation is less volatile. Such an outcome reflects the different magnitude of the policy response with respect to the sectoral inflation rates expressed by the optimal values of the parameters $k_1$ and $k_2$. However, in both cases, strict fulfillment of the inflation objectives comes at the expense of higher volatility of the output gap and relative prices and generates negative welfare effects. Therefore, the rule that accounts for both the output gap and inflation goals (rule 2) outperforms the strict inflation-targeting regimes. Moreover, the rule that stabilizes the traded and non-traded output gaps separately (rule 3) allows the standard deviations of the sector-specific variables to be brought closer to the optimal values and, at the same time, reduces the volatility of relative prices. Rule 4, which includes lagged domestic inflation, provides further welfare improvements and induces nearly optimal volatility of non-traded inflation, the variable which has the highest weight in the loss function. Finally, regime (5), which displays the features of an open economy, i.e., prescribes a certain degree of exchange rate management, performs well in terms of relative price stabilization but implies higher variation in non-traded inflation. In particular, an 8.5% decrease in the standard deviation of the exchange rate results in a 22.5% increase in the volatility of non-traded goods inflation and an 11.8% increase in the standard deviation of domestic inflation. Adopting rule 7, which targets sector-specific inflation rates in addition to total output and the exchange rate, allows more efficient reallocation of the response to deviations in sectoral price changes and thus yields a superior welfare outcome.

The results of this section demonstrate the tension between the objectives of domestic inflation and real exchange rate stabilization as well as the inflation-output gap policy trade-off common in the literature. We also numerically assess the welfare benefits of differentiating the policy response depending on economic sectors compared to stabilizing aggregate variables. Moreover, we show that the welfare results achieved under the “sector-specific” targeting rules can be closely replicated by a rule with an appropriate combination of aggregate variables, namely, the total output gap and the exchange rate. Therefore, responding to the open economy terms may contribute to welfare improvements when the central bank does not have enough information about sector-specific variables.

The exercise presented in this section has important practical implications. In particular, it could provide policymakers with a tool for analyzing the relative importance of monetary policy objectives and facilitate the design of a strategy aimed at achieving several competing goals.

7. Conclusions

In this paper we analyzed the stabilization objectives of optimal monetary policy in a two-sector small open economy model obtained as a limiting case of a two-country DSGE framework. We assessed the role of general preferences, structural asymmetries, and multiple relative prices in monetary policy design and welfare evaluation. The stabilization objectives derived for our model specification and represented by the loss function display the features of an open economy and reflect a multisectoral economic structure. Specifically, it is shown that social welfare is affected by deviations in inflation rates and output gaps (with sector-specific weights) as well as in relative prices from their target values. Therefore, the micro-founded welfare objective function differs from the ad hoc forms widely assumed in the applied literature. The exposure of one of the domestic sectors to the external environment not only determines the presence of open economy terms in the loss function, but also affects the decomposition of weights between domestic variables. In particular, the sector that is open to trade is allowed to adjust more at the optimum compared to the sector that produces goods for internal consumption only. Such a result implies a qualitatively different magnitude of the response to deviations in sector-specific variables compared to the closed economy setting and determines the asymmetric response of the domestic sectors to various
shocks. We characterized the optimal policy by the optimal targeting rule, which is a rather complex expression.

Finally, we experimented with alternative simple rules and analyzed their ability to replicate the optimal solution. The numerical results suggest that the type of shock is an important determinant of the comparative performance of optimal versus simple policy rules. Specifically, the optimal responses differ the most from the simple rules under fiscal and mark-up shocks. On the contrary, the DIT regime better approximates the optimal plan under foreign and productivity shocks.

An analysis of the welfare implications of alternative simple rules suggests that strict targeting of domestic and CPI inflation does not yield the best approximations for the optimal policy, and social welfare can be improved by accounting for other policy objectives, namely, the output gap and the exchange rate. We presented a ranking of alternative simple rules and evaluated the welfare benefits of targeting sector-specific versus aggregate variables. In addition, we showed that the rules which stabilize sector-specific output gaps can be closely replicated by a rule that responds to the aggregate output gap and the exchange rate. Such a result is important because a strategy which differentiates the response between domestic sectors is difficult to design and implement in practice. Generally, the simple rules perform quite well in terms of macroeconomic stabilization (relative to the optimal rule) and can deliver reasonable welfare results. An analysis of macroeconomic volatility under the simple rules demonstrated that our model generated an endogenous conflict between the objectives of domestic inflation and real exchange rate stabilization in addition to the inflation-output gap policy trade-off common in the literature.

In general, the analysis of optimal monetary policy based on micro-foundations which we employed in this paper enabled us to uncover important effects and incentives that arise in an open multisectoral economy. We were able to provide a welfare analysis based on economic fundamentals. Moreover, alternative simple rules were ranked according to a rigorous (but tractable) welfare measure. At the same time we would like to underline the drawbacks of such a methodological approach. In particular, the model lacks inflation inertia and persistence. This is a common disadvantage of the New Keynesian class of models, which do not reflect the actual dynamics of inflation and output. Therefore, we restrict our analysis to rather normative conclusions and admit the limited use of such models for forecasting purposes. However, we are convinced that the micro-founded and so-called reduced form approaches should interact in a complementary way in order to provide the appropriate policy recommendations. In fact, a comparative assessment of the monetary policy prescriptions derived in more applied studies versus the optimal reactions based on micro-foundations would be an interesting point for further analysis.

8. Mathematical Appendix

8.1 Second-Order Approximation to the Utility Function and Equilibrium Conditions

We apply the methodology described in Woodford (2003) and Benigno and Woodford (2005) in order to obtain the second-order approximation to the utility function of the form:

\[ U^j_t = E_t \left\{ \sum_{s=t}^{\infty} \beta^{s-t} [U(C^j_s) - V(y_s, T(j), A^i_{s,T}) - V(y_s, N(j), A^i_{s,N})] \right\} \quad (1) \]

We assume that preferences have isoelastic functional form and we arrive at the following expression:

\[ W_{t_0} = UCCC_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} x \]

\[ \begin{bmatrix} \hat{C}_t - (\bar{\mu}_N)^{-1} \gamma \hat{Y}_{N,t} - (\bar{\mu}_H)^{-1} (1 - \gamma) \hat{Y}_{H,t} + \frac{1}{2} (1 - \rho) \hat{C}^2_t \\ -\frac{1}{2} (\bar{\mu}_N)^{-1} \gamma (1 + \eta) \hat{Y}^2_{N,t} - \frac{1}{2} (\bar{\mu}_H)^{-1} (1 - \gamma) (1 + \eta) \hat{Y}^2_{H,t} \\ + (\bar{\mu}_N)^{-1} \gamma \eta \hat{A}_{N,t} \hat{Y}_{N,t} + (\bar{\mu}_H)^{-1} (1 - \gamma) \eta \hat{A}_{H,t} \hat{Y}_{H,t} \\ -\frac{1}{2} \gamma (\bar{\mu}_N)^{-1} \eta \pi^2_{N,t} - \frac{1}{2} (1 - \gamma) \frac{\sigma}{\bar{\mu}_H} \pi^2_{H,t} + t.i.p + (||\xi^3||) \end{bmatrix} \]

where \( t.i.p. \) denotes terms that are independent of policy and \( (||\xi^3||) \) denotes terms that are of third order and higher. We can write (2) in a vector-matrix form as:

\[ W_{t_0} = UCCC_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} x \]

\[ \begin{bmatrix} z'_t x_t - \frac{1}{2} z'_t Z_t x_t - x'_t Z_t \xi_t - \frac{1}{2} z'_{\pi H} \pi^2_{H,t} - \frac{1}{2} z'_{\pi N} \pi^2_{N,t} \end{bmatrix} + t.i.p + (||\xi^3||) \quad (3) \]

where

\[ x'_t \equiv \begin{bmatrix} \hat{Y}_{H,t} & \hat{Y}_{N,t} & \hat{C}_t & \hat{P}_{HT,t} & \hat{P}_{NT,t} \end{bmatrix} \]

\[ \xi'_t \equiv \begin{bmatrix} \hat{A}_{H,t} & \hat{A}_{N,t} & \hat{\mu}_{H,t} & \hat{\mu}_{N,t} & \hat{g}_{H,t} & \hat{g}_{N,t} & \hat{C}^*_t & \hat{P}^*_{NT,t} \end{bmatrix} \]

\[ z'_x \equiv \begin{bmatrix} (- (\bar{\mu}_H)^{-1} (1 - \gamma)) & (- (\bar{\mu}_N)^{-1} \gamma) & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \]

\[ Z_x \equiv \begin{bmatrix} (\bar{\mu}_H)^{-1} (1 - \gamma) (1 + \eta) & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & (\bar{\mu}_N)^{-1} \gamma (1 + \eta) & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -(1 - \rho) & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \]

\[ Z_\xi \equiv \begin{bmatrix} - (\bar{\mu}_H)^{-1} (1 - \gamma) & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & - (\bar{\mu}_N)^{-1} \gamma \eta & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \]
where \( k_L = \frac{(1-\alpha_L \beta)(1-\alpha_L)}{\alpha_L(1+\sigma)} \), for \( L = H, N \).

We now derive the second-order approximation to the structural equilibrium conditions. Following Benigno and Woodford (2005), we approximate the optimal price-setting equation (expression (10) in the main text) for both domestic sectors as well as the law of motion for the sectoral price indexes (11). We combine the corresponding expressions and, after integrating forward, obtain the following relations:

\[
V_0^H = E_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \times \left\{ \left[ \eta \hat{Y}_{H,t} + \rho \hat{C}_t - \hat{P}_{HT,t} + \gamma \hat{P}_{NT,t} + \hat{\mu}_{H,t} - \eta \hat{A}_{H,t} \right] + \frac{1}{2} \gamma (1 - \omega) (1 - \gamma) \hat{P}_{NT,t}^2 \right\} + \text{s.o.t.i.p. (}\|\xi^3\|\) \tag{4}
\]

\[
V_0^N = E_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \times \left\{ \left[ \eta \hat{Y}_{N,t} + \rho \hat{C}_t - (1 - \gamma) \hat{P}_{NT,t} + \hat{\mu}_{H,t} - \eta \hat{A}_{N,t} \right] + \frac{1}{2} \gamma (1 - \omega) (1 - \gamma) \hat{P}_{NT,t}^2 \right\} + \text{s.o.t.i.p. (}\|\xi^3\|\) \tag{5}
\]

where \( \text{s.o.t.i.p.} \) denotes second-order terms independent of policy. We can present equations (4) and (5) in a vector-matrix form as:

\[
V_0^H = E_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ a_x' x_t + a_x' \xi_t + \frac{1}{2} a_x' A_x x_t + x_t A_x \xi_t + \frac{1}{2} a_x' \pi_x^2 \right] + \text{s.o.t.i.p. (}\|\xi^3\|\) \tag{6}
\]

\[
V_0^N = E_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ b_x' x_t + b_x' \xi_t + \frac{1}{2} b_x' B_x x_t + x_t B_x \xi_t + \frac{1}{2} b_x' \pi_x^2 \right] + \text{s.o.t.i.p. (}\|\xi^3\|\) \tag{7}
\]

where

\[
a_x' \equiv \begin{bmatrix} \eta & 0 & \rho & -1 & \gamma & 0 \end{bmatrix}
\]

\[
a_x'' \equiv \begin{bmatrix} -\eta & 0 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}
\]

\[
A_x \equiv \begin{bmatrix} \eta(2 + \eta) & 0 & \rho & -1 & \gamma & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ \rho & 0 & -\rho^2 & \rho & \rho \gamma & 0 \\ -1 & 0 & \rho & -1 & \gamma & 0 \\ \gamma & 0 & \rho \gamma & \gamma & -\gamma^2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}
\]
The traded-goods demand equation is of the form:

\[ Y_H = \left( \frac{P_T}{P} \right)^{-\omega} \left( \frac{P_H}{P_T} \right)^{-\theta} \times \left\{ v(1-\gamma)C + \left( \frac{1}{ER} \right)^{-\omega} \left[ \left( \frac{1}{v(P_H)^{\theta-1} + (1-v)} \right) \right]^{\frac{1}{\theta-\omega}} (1-\gamma^*) \tilde{v}^* C^* \right\} \tag{8} \]

We take the second-order expansion of (8) and obtain the following relation:

\[ \hat{Y}_{HT,t} = -[\theta + (\theta - \omega)v] \hat{P}_{HT,t} + \omega \gamma \hat{P}_{NT,t} + v \hat{C}_t + \omega \gamma (1-v) \hat{E}_R \hat{R}_t + (1-v) \hat{C}_t^* + \hat{g}_{H,t} \]

\[ \frac{1}{2} \nu(1-v) \hat{C}_t^2 + \frac{1}{2} \omega^2 v(1-v) \hat{E}_R \hat{R}_t^2 + \frac{1}{2} \omega(1-\omega) \gamma (1-\gamma) \hat{P}_{NT,t}^2 - \frac{1}{2} \nu \left[ (1-\theta)(\theta - \omega) - (\theta - \omega)^2 v^2 \right] \hat{P}_{HT,t}^2 - \omega v^2 \hat{E}_R \hat{R}_t \hat{P}_{HT,t} - \omega(1-v) \hat{E}_R \hat{R}_t \hat{C}_t + \]

\[ \gamma \hat{P}_{NT,t} \hat{g}_{H,t} + [\theta + v(\theta - \omega)] \hat{P}_{HT,t} \hat{g}_{H,t} + v \hat{C}_t \hat{g}_{H,t} - \omega(1-v) \hat{E}_R \hat{g}_{H,t} + s.o.t.i.p. + (\| \xi^3 \|) \]
In a vector-matrix form the expression above takes the following form:

\[
\sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ c'_x x_t + c'_\xi \xi_t + \frac{1}{2} x'_t C_x x_t + x'_t C_\xi \xi_t \right] + s.o.t.i.p. + (||\xi^3||) = 0
\]  

(10)

where

\[
c'_x \equiv \begin{bmatrix} -1 & 0 & v \hfill \hfill \hfill \hfill \theta + (\theta - \omega) v \hfill \hfill \hfill \omega \gamma \hfill \hfill \omega (1-v) \end{bmatrix}
\]

\[
c'_\xi \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & (1-v) & 0 \end{bmatrix}
\]

\[
C_x \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & v(1-v) & (\theta - \omega) v^2 & 0 & -\omega v (1-v) \\
0 & 0 & (\theta - \omega) v^2 & \frac{v}{(1-v)^2} \left[ (1-\theta)(\theta - \omega) - (\theta - \omega)^2 v^2 \right] & 0 & - (\theta - \omega) \omega v^2 \\
0 & 0 & 0 & 0 & \omega (1 - \omega) \gamma (1 - \gamma) & 0 \\
0 & 0 & -\omega v (1-v) & - (\theta - \omega) \omega v^2 & 0 & \omega^2 v (1-v) \end{bmatrix}
\]

\[
C_\xi \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -v & 0 & -v (1-v) & 0 \\
0 & 0 & 0 & \theta + v(\theta - \omega) & 0 & -(\theta - \omega) v^2 & 0 \\
0 & 0 & 0 & -\omega \gamma & 0 & 0 & 0 \\
0 & 0 & 0 & -\omega (1-v) & 0 & \omega v (1-v) & 0 \end{bmatrix}
\]

Similarly, the demand equation for non-traded goods takes the following form:

\[
Y_N = \left( \frac{P_N}{P} \right)^{-\omega} \gamma C
\]  

(11)

The second-order approximation of this equation yields the following expressions:

\[
\tilde{Y}_{N.t} = \tilde{C}_t - w(1-\gamma) \tilde{P}_{NT,t} + \tilde{g}_{N.t} + \frac{1}{2} (1-\gamma) \omega (1-\omega) \tilde{P}_{NT,t}^2 - \tilde{C}_t \tilde{g}_{N,t} + \omega (1-\gamma) \tilde{P}_{NT,t} \tilde{g}_{N,t} + (||\xi^3||)
\]  

(12)

\[
\sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ d'_x x_t + d'_\xi \xi_t + \frac{1}{2} x'_t D_x x_t + x'_t D_\xi \xi_t \right] + s.o.t.i.p. + (||\xi^3||) = 0
\]  

(13)

\[
d'_x \equiv \begin{bmatrix} 0 & -1 & 1 & 0 & - w(1-\gamma) & 0 \end{bmatrix}
\]

\[
d'_\xi \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}
\]
\[ D_x \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & (1 - \gamma) \gamma \omega (1 - \omega) & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \]

\[ D_\xi \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \omega (1 - \gamma) & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \]

The second-order approximation of the risk-sharing equation (9) in the main text takes the form:

\[ \hat{C}_t = \frac{1}{\rho} E R_t + \hat{C}_t^* \]  

(14)

\[ \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ e'_x x_t + e'_\xi \xi_t + \frac{1}{2} x'_t E_x x_t + x'_t E_x \xi_t \right] + s.o.t.i.p. + (\|\xi^3\|) = 0 \]  

(15)

\[ e'_x \equiv \begin{bmatrix} 0 \\ 0 \\ -1 \\ 0 \\ 0 \end{bmatrix} \frac{1}{\rho} \]

\[ e'_\xi \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \]

\[ E_x = 0 \quad E_\xi = 0 \]

Finally, the real exchange rate equation (12) approximated up to the second order takes the form:

\[ v \hat{P}_{HT,t} = -(1 - \nu) E R_t - \gamma(1 - \nu) \hat{P}_{NT,t} + \gamma^*(1 - \nu) \hat{P}_{NT,t}^* - \frac{1}{2} \frac{(1 - \nu)}{\nu} (1 - \theta) \hat{E} R_t^2 - \frac{1}{2} \gamma(1 - \nu) \left[ \frac{\gamma(1 - \theta)}{\nu} + (1 - \omega)(1 - \gamma) \right] \hat{P}_{NT,t}^2 - \gamma^* \frac{(1 - \nu)}{\nu} (1 - \theta) \hat{E} R_t \hat{P}_{NT,t} + \frac{(1 - \nu)}{\nu} (1 - \theta) \gamma^* \hat{E} R_t \hat{P}_{NT,t}^* + s.o.t.i.p. + (\|\xi^3\|) \]  

(16)

\[ \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ f'_x x_t + f'_\xi \xi_t + \frac{1}{2} x'_t F_x x_t + x'_t F_\xi \xi_t \right] + s.o.t.i.p. + (\|\xi^3\|) = 0 \]  

(17)

\[ f'_x \equiv \begin{bmatrix} 0 \\ 0 \\ 0 \\ -\gamma(1 - \nu) \end{bmatrix} \]
We combine constraints (6), (7), (10), (13), (15), and (17) in order to get rid of the linear terms in the objective function (3). We collect vectors that contain the linear components of the above constraints and derive the vector \( \lambda \), such that:

\[
\begin{bmatrix}
a_x & b_x & c_x & d_x & e_x & f_x
\end{bmatrix} \times \lambda = z_x
\]

We solve the system of linear equations using the symbolic Matlab toolbox and derive values \( \lambda_1 - \lambda_6 \) associated with each of the constraints. After the linear terms cancel, we obtain the following expression for the loss function:

\[
L_{t0} = U_C \bar{C}E_{t0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ \frac{1}{2} x_t' \bar{Z}_x x_t + \frac{1}{2} x_t' \bar{Z}_x \xi_t + \frac{1}{2} \bar{Z}_\pi \pi_{H,t}^2 + \frac{1}{2} \bar{Z}_\pi \pi_{N,t}^2 \right] + K_0 + t.i.p + (||\xi^3||)
\]

where

\[
\bar{Z}_x = Z_x + \lambda_1 A_x + \lambda_2 B_x + \lambda_3 C_x + \lambda_4 D_x + \lambda_5 E_x + \lambda_6 F_x
\]

\[
\bar{Z}_\xi = Z_\xi + \lambda_1 A_\xi + \lambda_2 B_\xi + \lambda_3 C_\xi + \lambda_4 D_\xi + \lambda_5 E_\xi + \lambda_6 F_\xi
\]

\[
\bar{Z}_\pi = z_\pi + \lambda_1 a_\pi
\]

\[
\bar{Z}_\pi = z_\pi + \lambda_2 b_\pi
\]

\[
K_0 \equiv U_C \bar{C} \left[ \lambda_1 V_0^H + \lambda_2 V_0^N \right]
\]

Vectors \( \bar{Z}_x, \bar{Z}_\pi, \bar{Z}_\pi \) represent the weights next to the endogenous variables in the objective function.
Furthermore, we would like to present the loss function (18) in terms of the variables \( \hat{Y}_{H,t}, \hat{Y}_{N,t}, \hat{E}R_t, \hat{P}_{NT,t} \). Thus, we map the vector of all endogenous variables \( x'_t \equiv \begin{bmatrix} \hat{Y}_{H,t} & \hat{Y}_{N,t} & \hat{P}_{NT,t} & \hat{E}R_t \end{bmatrix} \) into the variables of interest with the use of matrices \( Q \) and \( Q_{\xi} \) such that:

\[
x_t = Q \begin{bmatrix} \hat{Y}_{H,t} & \hat{Y}_{N,t} & \hat{P}_{NT,t} & \hat{E}R_t \end{bmatrix}' + Q_{\xi} \xi_t
\]

(19)

and

\[
Q = \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
(1-\gamma) & -\gamma(1-\gamma)(l+1-v) & 0 & -(1-\gamma)(l+1-v) \\
0 & 0 & -\gamma(l-1) & -\frac{\rho_{\nu}}{v} \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{bmatrix}
\]

\[
Q_{\xi} = \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & -\gamma & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

where \( l = (\rho_{\theta} - 1)(1 - v)(1 + v) \) and \( \tilde{l} = \rho_{\nu}(1 - v) \). Therefore, the loss function (18) can be expressed as follows:

\[
L_{t_0} = UCE_t \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ \frac{1}{2} X_t' W_x X_t + X_t' W_{\xi} \xi_t + \frac{1}{2} W_{\pi_H} \pi_{H,t}^2 + \frac{1}{2} W_{\pi_N} \pi_{N,t}^2 \right] + K_0 + t.i.p + (\| \xi^3 \|)
\]

(20)

where \( X_t = \begin{bmatrix} \hat{Y}_{H,t} & \hat{Y}_{N,t} & \hat{P}_{NT,t} & \hat{E}R_t \end{bmatrix} \), \( W_x = Q' \tilde{Z}_x Q \), \( W_{\xi} = Q' \tilde{Z}_\xi Q' + Q' \tilde{Z}_\xi Q_{\xi} + Q' \tilde{Z}_\xi Q_{\xi} \), \( W_{\pi_H} = \tilde{Z}_{\pi_H} \), \( W_{\pi_N} = \tilde{Z}_{\pi_N} \).

Finally, we present the variables in the objective function in terms of the deviations from their target values. Thus we denote the gap as \( \tilde{X}_t = (X_t - X_t^T) \). The target values are functions of the exogenous shocks and take the following general form: \( X_t^T = \left( -\frac{W_{\xi}}{W_{\pi}} \xi_t \right) \). As a result, we are able to present the objective function in the following quadratic form:

\[
L_{t_0} = UCE_t \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left[ \frac{1}{2} (X_t - X_t^T)' W_x (X_t - X_t^T) + \frac{1}{2} W_{\pi_H} \pi_{H,t}^2 + \frac{1}{2} W_{\pi_N} \pi_{N,t}^2 \right] + K_0 + t.i.p + (\| \xi^3 \|)
\]

(21)

Expression (21) corresponds to formula (29) in the main text.
