CNB WORKING PAPER SERIES

The Working Paper Series of the Czech National Bank (CNB) is intended to disseminate the results of the CNB's research projects as well as the other research activities of both the staff of the CNB and collaborating outside contributors, including invited speakers. The Series aims to present original research contributions relevant to central banks. It is refereed internationally. The referee process is managed by the CNB Research Department. The working papers are circulated to stimulate discussion. The views expressed are those of the authors and do not necessarily reflect the official views of the CNB.

Banks' Capital and Liquidity Creation: Granger Causality Evidence

Roman Horváth, Jakub Seidler, and Laurent Weill*

Abstract

This paper examines the relation between banks' capital and liquidity creation. This issue is of interest to determine the potential impact of higher capital requirements for banks on their liquidity creation, which may have particular importance with new Basel III reform demanding from banks higher capital. We perform Granger-causality tests in a dynamic GMM panel estimator framework on an exhaustive dataset of Czech banks from 2000 to 2010. We observe a strong expansion of liquidity creation during the full period, which was slowed by the financial crisis, and was mainly driven by large banks. We show that capital is found to negatively Granger-cause liquidity creation but also observe that liquidity creation Granger-causes capital reduction. These findings support the view that Basel III reforms demanding higher capital can reduce liquidity creation, but also that greater liquidity creation can have a detrimental impact by reducing bank solvency. We thus show that there might be a trade-off between the benefits of financial stability induced by stronger capital requirements and those of increased liquidity creation of banking sector.

JEL Codes: G21, G28.

Keywords: Bank capital, liquidity creation.

Nontechnical Summary

This paper examines the relation between capital and liquidity creation, which is a comprehensive measure of a bank's overall ability to finance relatively illiquid assets with relatively liquid liabilities and thereby serve as a financial intermediary. We test the relation between bank capital and liquidity creation by using an exhaustive dataset of Czech banks from the Czech National Bank from 2000 to 2010. This way, we focus on causal relation between banks capital and liquidity creation and thus propose broad perspective on their reciprocal interactions in the banking industry. In doing so, we are able to provide evidence on the potential detrimental impact of capital requirements on liquidity creation, which is highly relevant for appraising the economic implications of the capital requirements in the Basel III reforms.

We show that capital is found to negatively Granger-cause liquidity creation. However, we also observe that liquidity creation Granger-causes capital reduction. We thus support the view that there is a negative, bi-causal relation between capital and liquidity creation, which corroborates the importance of examining this causality.

Our findings have two policy implications. First, they suggest that the Basel III Accords may lead to reduced bank liquidity creation by introducing tighter capital requirements. As a result, these new rules may contribute to the creation of alternative economic difficulties by reducing liquidity creation, which can slow economic growth through reducing the amount of available financing. Second, our findings support the view that symmetrically greater liquidity creation may hamper bank solvency.

Overall, our primary conclusion is that there is a trade-off between the benefits of financial stability induced by stronger capital requirements and those of greater liquidity creation. Therefore, any action in favor of one objective would deteriorate the other. We are fully aware that our findings may be dependent on our sample and may not be easily generalizable. However, the Basel III rules increasing capital requirements are planned to be implemented for a vast array of countries, including that examined here and others that are similar. In any case, to deepen our understanding of the relation between capital requirements and liquidity creation should occupy a high position on the bank regulation research agenda.

1. Introduction

Recent financial turmoil has led the Basel Committee on Banking Supervision to propose new capital rules, commonly known as the Basel III reforms. They are based on the conclusion that the financial crisis was rooted in low solvency levels on bank balance sheets. As a consequence, these reforms introduce tighter capital requirements. In particular, the objective is to improve the resilience of the banking industry: "A strong and resilient banking system is the foundation for sustainable growth, as banks are at the center of the credit intermediation process between savers and investors. Moreover, banks provide critical services to consumers (...)." (Basel Committee on Banking Supervision 2010, p.5).

Thus the Basel Committee emphasizes the importance of not only bank solvency, but liquidity creation as well, which is a key economic function of banks. Banks function as liquidity creators by financing relatively illiquid assets with relatively liquid liabilities. They thereby contribute to financing the economy and facilitating transactions between economic agents, or, to express it in Bank for International Settlements (BIS) terms, they contribute to credit intermediation and provide critical services to consumers.

This notion is extremely relevant, as higher capital requirements imposed by the Basel III may have a negative impact on liquidity creation of the banking sector. This view is also supported by recent work by Berger and Bouwman (2009) that measures bank liquidity creation in the US. Analyzing the role of capital in bank liquidity creation, they conclude to the impact of opposing effects which can lead to a liquidity-destroying effect of capital. However, this study does not consider the potential for reverse causality that could influence the debate on capital requirements and modify their interpretation.

Our aim in this paper is to examine the relation between capital and liquidity creation by testing their causal relation. We propose a broad perspective on the interactions between capital and liquidity creation in the banking industry. In doing so, we are able to provide evidence on the potentially detrimental impact of capital requirements on liquidity creation. This would suggest a conflict between bank solvency and liquidity creation.

A negative impact of capital on liquidity creation would suggest that greater capital requirements may hamper liquidity creation. In other words, there would be a trade-off between the benefits of financial stability induced by greater capital requirements and the costs of lower liquidity creation in the economy. This trade-off would be strengthened if liquidity creation was observed to have a negative effect on capital, as this would suggest that greater liquidity creation by banks may have detrimental effects on bank solvency. This reverse causality would also support the view that an optimal level of liquidity creation and capital might exist.

Reciprocally, finding a positive impact of capital would provide support for the implementation of stronger bank capital requirements in the Basel III Accords, as they would result in greater safety and in higher liquidity creation. Furthermore finding that liquidity creation on capital has a positive effect on capital would mean that greater liquidity creation can also contribute to bank solvency and thus would show the existence of a virtuous circle in favor of tightening capital requirements.

Therefore, our research helps to assess the economic implications of the capital requirements in the Basel III reforms. The potential costs of these reforms have been assessed by international organizations. While Angelini et al. (2011) for BIS estimate that an increase of 1 percentage point leads to 0.09 percent decline in output, an OECD study by Slovik and Cournède (2011) concludes that increased financing costs from following the new capital requirements reduce GDP growth by 0.05 to 0.15 percentage point annually. However, neither study explicitly considers the potential costs of reduced liquidity creation, which might lead to a reappraisal of the strengthening bank capital requirements included in the Basel III accords.

The theoretical and empirical literature provides conflicting assumptions about the relation between capital and liquidity creation, both in terms of sign and the type of causality. Berger and Bouwman (2009) proposed two contradictory hypotheses regarding the impact of bank capital on liquidity creation. Furthermore, the literature suggests mechanisms for the potential influence of liquidity creation on bank capital that do not accord on the expected sign.

The concept of liquidity creation used in this paper is a comprehensive measure of a bank's overall ability to transform maturity in the economy, rather than of the volume of assets in banks' balance sheets, which can be easily sold. Further, this measure accounts for both the on- and off-balance sheet activities of banks, as other studies have highlighted the importance of banks' off-balance sheet activities (e.g., Boot, Greenbaum, and Thakor 1993, Holmstrom and Tirole 1997, Kashyap, Rajan, and Stein 2002). Therefore, the liquidity creation measure is used instead of some other indicators that only capture a bank's lending activity (e.g., credit-to-total asset ratio).

We perform some Granger-causality tests to check the sign and the type of causal relation between bank capital and liquidity creation. We embed Granger causality estimations in GMM dynamic panel estimators to address the econometric complications induced by the use of lagged dependent variables. We then follow recent empirical studies on banking that similarly investigate causality in various banking issues such as the relation between non-performing loans and efficiency (e.g., Podpiera and Weill, 2008, for Czech banks; Fiordelisi, Marques-Ibanez and Molyneux, 2011, for European banks) or the link between competition and efficiency (e.g., Pruteanu-Podpiera, Weill and Schobert, 2008, for Czech banks; Casu and Girardone, 2009, for European banks).

We explore the relation between bank capital and liquidity creation using an exhaustive dataset of Czech banks from the Czech National Bank from 2000 to 2010. Our study is limited to a single country as it requires very detailed data. This requirement explains why all of the recent papers implementing Berger and Bouwman (2009)'s methodology are single-country studies. Measuring liquidity creation requires very detailed data because balance sheet items need to be classified to compute liquidity creation measures. As a consequence, cross-country databases such as Bankscope cannot be used because the information provided is not sufficiently disaggregated to allow for the use of such measures.¹

The Czech banking industry is an interesting case for our investigation. While it does not contain very large banks, it contains banks of various sizes. Therefore, an investigation of this banking

¹ For instance, Bankscope does not provide the disaggregation of loans by category or by maturity for the vast majority of banks, which is of course needed for the computation of liquidity creation measures. Moreover, even within countries, the classifications of demand deposits, savings deposits, and time deposits are not consistent across banks.

industry does not suffer from selection bias, as could be the case for any study focusing on large banks or listed banks. Furthermore, the detrimental effects of new bank capital requirements might be of particular importance for small banks, which face greater difficulties in increasing their capital. Therefore, an analysis of the impact of bank capital on liquidity creation must include small banks.

The Czech Republic is a former transition country and is now an EU member. The vast majority of Czech banks are foreign-owned. Thus, results found for this country can be generalized to countries with high levels of foreign bank ownership of banks rather than to any other countries.² However, the results still provide interesting insights that may be of interest in the policy debate, particularly as the causal relation between capital and liquidity creation has not been investigated previously. Moreover, as foreign bank entry is an important debate in many emerging countries, results obtained for a banking industry that is largely owned by foreign investors are of special interest to these countries.

The use of Czech data will also provide an opportunity to analyze the volume and evolution of liquidity creation in the Czech Republic over the last decade. We will then be able to examine whether the amount of liquidity created by Czech banks is similar to what Berger and Bouwman (2009) found for the US. It will also prove information on the evolution of aggregate liquidity creation over time. Importantly, we will investigate whether the financial crisis reduced liquidity creation and thereby worsened economic difficulties via this transmission channel.

The remainder of this paper is structured as follows. In section 2, we present the hypotheses and related literature and then describe recent changes in the Czech banking industry. Section 3 presents the methodology. Section 4 develops the results. We conclude in section 5.

2. Background

2.1. Hypotheses

Contradictory assumptions can be advanced regarding the relation between capital and liquidity creation. They diverge both in terms of the relation's sign and the type of causality.

Berger and Bouwman (2009) posited two hypotheses framing the causal link that moves from bank capital to liquidity creation. The risk absorption hypothesis predicts that increased capital enhances the ability of banks to create liquidity. This hypothesis stems from two strands of the literature concerning the role of banks as risk transformers. Liquidity creation increases the bank's exposure to risk because banks that create more liquidity will face greater losses when they are forced to sell illiquid assets to satisfy the liquidity demands of customers (e.g., Allen and Santomero, 1998; Allen and Gale, 2004), while bank capital allows the bank to absorb greater risk (e.g., Bhattacharya and Thakor, 1993 Repullo, 2004).

² Note that a large share of foreign bank ownership is common in Central and Eastern European countries. In addition to the Czech Republic, in Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Estonia, FYR Macedonia, Georgia, Hungary, Lithuania, Montenegro, Romania and Slovakia foreign banks own greater than 80% of bank assets. These figures come from EBRD Structural Change Indicators.

In contrast, the financial fragility hypothesis predicts that increased capital hampers liquidity creation (Diamond and Rajan, 2001). Briefly, the financial fragility effect is an outcome of the following process. The bank collects funds from depositors and lends them to borrowers. Once a loan is issued, the bank has to monitor the borrower and collect loan payments. This helps the bank obtain private information on its borrowers that gives it an advantage in assessing their profitability. However, this informational advantage creates an agency problem, whereby the bank may be tempted to extract rents from its depositors by demanding a greater share of the loan income. If depositors refuse to pay the higher costs, the bank threatens to curtail its monitoring or loan collection efforts. As depositors know that the bank may abuse their trust, they become wary of depositing their money with the bank. The bank is thus forced to demonstrate its commitment to depositors by adopting a fragile financial structure with a large share of liquid deposits. The result of this fragile financial structure is that the bank runs the risk of losing funding if it attempts to withhold depositors. As such, the threat of bank runs mitigates the holdup problem that arises after depositors have put their funds in the bank. Consequently, by allowing the bank to receive more deposits and finance more loans, financial fragility favors liquidity creation. As greater capital reduces financial fragility, it enhances the bargaining power of the bank and hampers the credibility of its commitment to the depositors. Thus, increased capital works to diminish liquidity creation.

However, we can also propose a mechanism through which the relation moves from liquidity creation to capital. The illiquidity risk hypothesis contends that greater liquidity creation increases the risk of illiquidity for banks because illiquid assets occupy a larger share of their total balance sheets. This incentivizes banks to strengthen their solvency through increased capital, not only so that they can still have a relaxed access to external funding markets but also because capital acts as a buffer because creating liquidity is risky. Therefore, greater liquidity creation should lead to higher levels of bank capital. This hypothesis is related to empirical works examining the impact of risk on bank capital buffers (Lindqist, 2004; Jokippi and Milne, 2011).

2.2 Related Literature

The literature on bank liquidity creation remains scarce because its expansion is a recent development in the wake of Berger and Bouwman (2009)'s pioneering article. This paper makes a major contribution by suggesting a new method for measuring the liquidity created by banks. They propose a classification of all balance sheet items as liquid, semi-liquid and illiquid. This applies to all items in a bank's assets, liabilities, equity, and off-balance sheet activities. They use different classifications for the items, leading to four different measures of liquidity creation. Two measures are based on category classification of balance sheet items, while two measures are based on maturity. For each type, one measure includes off-balance sheet activities, while the other does not. The authors then assign weights to all of the items and compute the amount of liquidity created by each bank.

Berger and Bouwman (2009) use this method to measure liquidity creation in the US banking industry between 1993 and 2003. They find that the US banking industry created \$2.8 trillion in liquidity in 2003 and liquidity creation increased substantially between 1993 and 2003. They also show that that large banks, multibank holding company members, retail banks, and recently merged banks create the most liquidity.

Berger and Bouwman explore the relation between bank capital and liquidity creation. They find that this relation varies with size and depending on whether off-balance sheet items are included in the liquidity creation measure. With measures including off-balance sheet items, the relation is positive for large banks, not significant for medium banks, and negative for small banks. With measures excluding off-balance sheet items, the relation is not significant for large and medium banks, and negative for small banks.

A handful of recent papers have followed this study. Fungáčová, Weill and Zhou (2010) extend the debate on the relation between bank capital and liquidity creation by analyzing how deposit insurance scheme affects this relation. To do so, they study Russia, which provides a natural experiment to investigate this issue because a deposit insurance scheme was implemented there in 2004. Even if the deposit insurance scheme has effects, its implementation does not change the sign of the relation. They find a negative relation between bank capital and liquidity creation before and after the deposit insurance scheme. Moreover, they observe that the relation varies with size and ownership. It is significantly negative for small and medium banks, and for private domestic banks, while it is not significant for large banks, foreign banks, and state-owned banks.

Berger and Bouwman (2010) analyze the impact of monetary policy on aggregate bank liquidity creation in the US. Analyzing the period from 1984 to 2008, they examine whether the impact differs between normal periods and financial crises, as well as with respect to bank size. They show that tightening monetary policy only reduces liquidity creation for small banks. This effect is weaker during financial crises. They also note that liquidity creation is somewhat higher prior to financial crises, which suggests that measures of aggregate liquidity creation have explanatory power in predicting crises.

Berger et al. (2012) investigate how regulatory interventions and capital injections influence risk and liquidity creation using a sample of German universal banks. They find that these interventions reduce both risk and liquidity creation. Rauch et al. (2011) analyze potential determinants of liquidity creation for a sample of German savings banks. They compare the influence of macroeconomic factors, including monetary policy and unemployment, with the bank-specific factors such as size or financial performance. They find some support for the impact of monetary policy, as monetary policy tightening reduces liquidity creation. However, bank-specific factors do not seem to have any influence on liquidity creation. Additionally, Pana, Park and Query (2010) examine the impact of bank mergers on liquidity creation for US banks. They report that mergers have a positive influence on bank liquidity creation.

2.3 The Evolution of the Czech Banking Industry

The banking industry occupies a dominant position in the Czech financial system and represents the most relevant channel of financial intermediation. While the depth of financial intermediation (measured as total financial sector assets to GDP) reached 156% at the end of 2010, the ratio of banking sector assets to GDP was nearly 115% according to figures from the Czech National Bank. The banking sector's large share of the overall financial system has been relatively stable in recent years (see Figure 1). However, compared to Eurozone countries, the Czech financial sector remains relatively underdeveloped.

The 1990s was the first decade of a marked-based banking sector and was characterized by the deleveraging and cleaning of bank portfolios, which were primarily concentrated in the corporate sector. These loans were of dubious quality as a legacy of the centrally driven economy and poor asset management during this period. The banking sector underwent restructuring and privatization through 2001. As a result, approximately 97 percent of banking sector assets is currently owned by foreign capital, predominantly from other EU countries.

After the restructuring of the banking sector and in line with the solid performance of the Czech economy, bank credit to the private sector grew substantially during the 2003–2007 period. Nonetheless, this relatively rapid credit growth – especially to the household sector – was primarily financed through local currency deposits, and banks had no incentive to offer foreign currency loans. Thus, the Czech Republic is one of a small number of countries in the Central and Eastern European region that neither experienced a boom in foreign currency lending nor relied on external (foreign) funding. The increased lending to households was primarily conducted in the local currency, which mitigated potential future risk from exchange rate depreciation.

As a result, the performance of the Czech banking sector improved significantly after 2001, which is made apparent by high capital buffers (approximately 15% at the end of 2010) and relatively small non-performing loans ratio (6.2% in 2010). This also led to a relatively mild impact of the financial crisis in 2009, and no Czech bank needed government support.

The Czech banking sector is considered to be well funded because approximately 70% of liabilities are created by client deposits. This also illustrates that the ratio of deposits to loans in the Czech Republic is among the highest in the EU, as observed in Figure 2.

3. Methodology

3.1 Measures of Bank Liquidity Creation

We use data for all Czech banks during the period 2000–2010 from the Czech National Bank.³ The data come from the balance sheets of banks that are reported to CNB Banking Supervision of the central bank, and we have an unbalanced panel of 31 banks with 3,821 monthly observations.

We compute two measures of liquidity creation. We follow Berger and Bouwman (2009)'s procedure by classifying items on Czech banks' balance sheets as liquid, semi-liquid and illiquid. Once all of the balance sheet items are classified as liquid, semi-liquid or illiquid, we assign them weights and calculate the measures of liquidity creation by summing all weighed items. We apply the weights as in Berger and Bouwman (2009) for illiquid assets (weight ½), semi-liquid assets (weight 0) and liquid assets (weight -1/2). We agree with that study that this classification is a necessary simplification. However, a finer distinction would be rather arbitrary. The formula for liquidity creation is as follows:

```
Liquidity Creation = \{\frac{1}{2} \times \text{ illiquid assets} + 0 \times \text{ semi-liquid assets} - \frac{1}{2} \times \text{ liquid assets} \} +
                                 + \{ \frac{1}{2} \times \text{ liquid liabilities} + 0 \times \text{ semi-liquid liabilities} - \frac{1}{2} \times \text{ illiquid liabilities} \}
```

Berger and Bouwman (2009) propose four different measures of liquidity creation, which differ with respect to the classification of balance sheet items. Their specifications use a classification based on the categories or maturities of items ("cat" or "mat" measures) and include or exclude offbalance sheet items ("fat" or "nonfat" measures). We only use the classification based on maturity of items, as our dataset provides detailed information that allows us to consider on- and off-balance sheet items by maturity, which is not the case for the classification by category. Our measures differ with respect to the inclusion of off-balance sheet items. Hence, in Berger and Bouwman's terminology, we consider the "mat fat" liquidity creation measure and the "mat nonfat" liquidity creation measure that we label, respectively, the broad and the narrow liquidity creation measures for the purposes of our analysis.

It is worth emphasizing that we do not use exactly the same definition that Berger and Bouwman employed for US banks. Our approach is "fully mat fat", i.e., all items are classified by the remaining maturity. Berger and Bouwman classify items on the asset side according to maturity; nevertheless, they classify loans entirely by either product category or by maturity and do not combine this information as they do for other bank activities. Concerning the liabilities and equity, they adopt the same classification based on category. Therefore, it has to be noted that our liquidity creation indicator represents a slightly different measure of liquidity creation, which is based solely on the detailed remaining maturity maturities of the balance sheet items not only on the asset side but also for liabilities and equity.⁴

³ Czech banks in this analysis also include all foreign-owned subsidiaries but not foreign bank branches, which only represent 11.5% of the total assets in the Czech banking sector (as of the end-2011).

⁴ Furthermore, when we calculate the maturity of corporate loans based on the categories of companies' various economic activities (e.g., agriculture, mining, manufacturing, etc.) using the data on all individual loans issued to corporations in the Czech Republic available in the Central Credit Register dataset, we find that the average maturity does not differ significantly for many economic sectors. For example, the average loan maturity for firms

The broad measure of liquidity creation is our preferred one because it accounts for off-balance sheet items that can also provide liquidity and is thus more comprehensive. Nevertheless, the narrow measure is relevant for our analysis, as it allows us to check the robustness of our conclusions. Table 1 gives a detailed description of the classification.

3.2 The Granger Causality Framework

To test the hypotheses on the relation between bank capital and liquidity creation, we employ the Granger-causality framework. We thus estimate the following equations to examine the intertemporal relations between bank capital and liquidity creation:

$$LiquidityCreation_{i,t} = f(Capital_{i,lag}, LiquidityCreation_{i,lag}, Z_{i,t}) + e_{i,t}$$
 (1)

$$Capital_{i,t} = f(LiquidityCreation_{i,lag}, Capital_{i,lag}, Z_{i,t}) + e_{i,t}$$
(2)

where the subscript t denotes the time dimension, i represents the cross-sectional dimension across banks, Z represents the control variables and $e_{i,t}$ is the error term. LiquidityCreation is the ratio of liquidity creation to assets. We will use the broad and narrow measures of bank liquidity creation to shed light on the robustness of our results even though, as mentioned above, the broad measure is preferred because it includes off-balance sheet items. Capital is the ratio of bank equity to total assets.

Equation (1) tests whether changes in capital temporally precede variations in liquidity creation, while equation (2) evaluates whether changes in liquidity creation temporally precede variations in capital. We use four lags, which appears reasonable given the monthly frequency of our data. In their analyses of the causal relation between non-performing loans and bank efficiency, Podpiera and Weill (2008) use three lags and Fiordelisi, Marques-Ibanez and Molyneux (2011) choose two lags, but they have yearly data.

We estimate an AR(4) process in which Granger-causality is tested by a joint test that the sum of all of the lagged coefficients of the explained variable in question is significantly different from zero. The introduction of lagged dependent variables in the predicting variables creates econometric problems induced by unobserved bank-specific effects and joint endogeneity of the explanatory variables. To address these issues, we use the system GMM estimators developed for dynamic panel models by Arellano and Bover (1995) and Blundell and Bond (1998). Podpiera and Weill (2008) and Fiordelisi, Marques-Ibanez and Molyneux (2011) used similar frameworks of a Granger-causality test embedded in GMM dynamic panel estimators.

We include a series of control variables. The selection of variables is partly driven by the work of Berger and Bouwman (2009) on US banks, as they also regress liquidity creation on capital by

in mining is 3.8 years, for manufacturing is 4.3 years and for construction is 3.7 years. As a result, for the Czech data, it is less fruitful to classify some loan categories as liquid, while other categories as semi-liquid or illiquid.

controlling for several factors. Nevertheless, we add additional control variables to account for the specific characteristics of the country under analysis and consider some potential determinants of capital to assets ratios, which was not a dependent variable for Berger and Bouwman.

We take various dimensions of risk into account using three variables: Earnings Volatility, defined as the standard deviation of the bank's monthly return on assets measured over the previous six months, Credit Risk, which is the ratio of risk-weighted assets and off-balance sheet activities divided by assets, and Z-Score, measured by the return on assets plus Capital divided by Earnings Volatility. We also control for Non Performing Loans with the ratio of non-performing loans to total loans for two reasons. On the one hand, many Czech banks had portfolios with a sizeable amount of non-performing loans because of the banking reforms implemented in the 1990s at the beginning of the period of our study. On the other hand, our study covers the recent financial crisis, in which the share of non-performing loans increased somewhat. The risk measures are not orthogonalized, as their correlation is low.

We consider Size, measured by the log of total assets, and Market Share, defined as the market share of total deposits for each bank. As we use monthly data at, we include Inflation and Unemployment to control for the macroeconomic environment. These macroeconomic data come from the Czech Statistical Office.

Unlike Berger and Bouwman (2009), we do not include a dummy variable for mergers and acquisitions, as there were very few during our sample period and the dummy would be largely correlated with the constant. Similarly, we do not include any variables that capture population density, as the Czech Republic is a rather small country and banks typically do not specialize geographically. Table 2 displays summary statistics for all of the variables used in the estimations.

4. Results

This section displays our results. We first provide evidence on the volume and evolution of liquidity creation by Czech banks. We then develop estimations of the relation between capital and liquidity creation.

4.1 Analysis of Liquidity Creation

We study the volume and evolution of bank liquidity creation. To do so, we provide liquidity creation measures for all banks. We also separately consider four categories of Czech banks: large banks (with total assets of more than CZK 200 billion, approximately 11.3 billion USD), mediumsized banks (total assets between CZK 50 billion and 200 billion, approximately 2.8–11.3 billion USD), small banks (total assets less than CZK 50 billion), and building societies.⁵ This decomposition allows us to draw conclusions about the roles that the different categories of banks

⁵ A building society is a special type of bank that provides home loans to households under specific conditions given in Act No. 96/1993 Coll., on Building Savings Schemes and State Support for Building Savings Schemes and its later amendments. Based on the volume of total assets, 4 building societies would be classified as mediumsized banks and one as a small bank.

play in liquidity creation. Table 3 provides the results for the liquidity creation measures over the period. They are also presented in Figures 3 and 4 for the broad and the narrow liquidity creation measures, respectively. Several conclusions are apparent.

First, we observe a strong expansion of liquidity creation during the full period. The aggregate volume of liquidity creation, when using the broad measure, increased in real terms from 357.1 billion CZK in 2000 (approximately 20.2 billion USD) to 1,293.8 billion CZK in 2010 (approximately 73.1 billion USD). The mean ratio of liquidity creation to assets more than doubled from 15% in 2000 to 33% in 2010. The same findings are observed when we use the narrow measure of liquidity creation.

These changes are in line with developments in the Czech banking industry. The high growth in liquidity creation in 2001–2003 was stimulated by the decline in interest rates to levels similar to those in the Euro zone, following the successful disinflation. They were also driven by the consolidation of the banking industry, as larger banks are associated with greater liquidity creation. The growth peaked again at the onset of the global financial crisis. This is likely linked to high economic growth associated with considerable credit growth. Bank prudence increased during the global financial crisis, which contributes to halting the growth of liquidity creation. However, the crisis was not associated with the decline in liquidity creation. This development likely reflects the good financial health of the Czech banking sector, as banks that are in better shape have less incentives to reduce their credit supply. The positive financial situation of Czech banks is supported by the observation that, unlike in most EU countries, these banks did not benefit from any governmental support during the crisis, and stress tests suggest that they are able to withstand considerable negative shocks (Czech National Bank, 2011).

Second, large banks contribute widely to liquidity creation. In 2000, large banks were responsible for 88% of total liquidity creation. Over the 2000s, their contribution to liquidity creation decreased somewhat but remained highly important: they represented 69% of total liquidity creation in 2010. This reduction is a consequence of the increasing role of medium-sized banks and building societies in liquidity creation over time. Small banks created very little liquidity during the full period. We hypothesize that this is due to their somewhat weaker lending activity. The key role of large banks in liquidity creation is in accordance with what Berger and Bouwman observe for the US banking industry. They show that large banks created 81% of total liquidity in 2003. This result is primarily driven by the creation of long-term maturity assets from short-term maturity liabilities, which is related to the high deposit-to-loan ratio of the Czech banking sector (Figure 2).

However, one may wonder whether large banks create more liquidity relative to their size. Namely, large banks can contribute more to liquidity creation in absolute terms, but might create less liquidity in relative terms when considering their total assets. The analysis of the ratios of liquidity creation to assets confirms the predominant role of large banks in liquidity creation in relative terms. The mean ratios for large banks are 18% in 2000 and 39% in 2010, compared with means for all banks of 15% in 2000 and 33% in 2010.

Third, comparisons for both liquidity creation measures show that off-balance sheet items play a small role in liquidity creation. This differs from the US situation described in Berger and Bouwman: while off-balance sheet items contribute approximately 50% to the overall bank liquidity creation in the US, they only contribute approximately 10% in the Czech Republic. For

example, building societies have almost no off-balance sheet items, which reflects regulatory issues. Interestingly, off-balance sheet items destroy rather than create liquidity in the Czech Republic. Nevertheless, it has to be acknowledged that the differences between our and Berger and Bouwman (2009)'s results may be driven by differences in the methods used to calculate liquidity creation. For example, our approach classifies loan commitments with short maturities as liquid with a weight of -1/2 thus destroying liquidity. In contrast, Berger and Bouwman (2009) classify loan commitments of any maturity as illiquid, arguing that it is equally hard to get rid of a shortterm loan commitment as a long-term loan commitment.

4.2 Regressions

We now turn to the regressions we run to investigate the sign and sense of causality between capital and liquidity creation. We focus our estimations on the broad measure of liquidity creation. Table 4 contains the results. The dependent variable is Capital or Liquidity Creation. We test two alternative specifications of the set of control variables by including or excluding both macroeconomic variables, Inflation and Unemployment, to examine their potential influence on the results.

We show that capital is found to negatively Granger-cause liquidity creation, as the sum of the lagged variables for Capital is significantly negative for both models with Liquidity Creation as the dependent variable. This finding speaks in favor of the financial fragility hypothesis, according to which greater capital contributes to a deterioration of liquidity creation.

Berger and Bouwman (2009) also find a negative impact of capital on liquidity creation but only for small banks. Hence our results for Czech banks diverge from their findings for US banks. At first glance, one could imagine that Czech banks are not large enough to make the sign positive. However, comparing the sizes of US and Czech banks rejects this view. The mean balance sheet for Czech banks is 105 billion CZK, i.e., 6 billion USD, with a maximum size exceeding 770 billion CZK, i.e., 45 billion USD, which has to be compared with a mean size of 10 billion USD for US large banks in the abovementioned paper. In other words, Czech banks are not smaller than US banks on average. Thus, our results tend to show a more detrimental influence of capital on liquidity creation in the Czech case. Our findings are in accordance with the observation from Fungáčová, Weill and Zhou (2010) on Russian banks, which concludes that capital has a significantly negative impact on liquidity creation. Ultimately, this tends to suggest that the US findings on this impact cannot be generalized.

When we study the reverse causality, we observe that liquidity creation negatively Granger-causes capital reduction because the sum of the lagged variables for *Liquidity Creation* is significantly negative for both specifications with Capital as the dependent variable. In other words, greater liquidity creation leads to lower levels of bank capital. We can interpret this finding through a crowding-out effect, according to which increased liquidity creation is associated with increased deposits that crowd out capital. More generally, improved access to the depositor base would reduce the incentives for bank managers to search for external funding, including capital.

This latter finding is of the utmost importance. First, it shows the importance of investigating the reverse causality between capital and liquidity creation that was previously ignored in the literature. Second, a bi-causal, negative relation between capital and liquidity creation stresses the existence of a trade-off for authorities between bank solvency, with high capital levels, and liquidity creation.

To sum it up, our regressions show that there is a bi-directional link between capital and liquidity creation that is negative.

Turning to the analysis of the control variables, we observe that most control variables are not significant. One notable feature is the significantly negative coefficient for *Unemployment*, which means that greater unemployment deteriorates both capital and liquidity creation. This finding is in accord with the fact that banks suffer from a reduction in solvency and create lower liquidity in troubled economic times.

4.3 Robustness Checks

We perform alternative estimations to determine whether our findings are robust to the chosen measure of liquidity creation, to the period of study, and to the frequency of data.

In a first robustness check, we rerun all estimations by using the narrow measure of liquidity creation. Thus far, we have focused on the broad measure of liquidity creation. However, the results might differ when off-balance sheet activities are excluded. The results are displayed in Table 5. Interestingly, they show a similar pattern in the relation between capital and liquidity creation. The total effect of capital on liquidity creation is again significantly negative, while we find the same conclusion for the total effect of liquidity creation on capital. The sums of the lagged variables for *Capital* when explaining *Liquidity Creation* and for *Liquidity Creation* when explaining *Capital* are still significantly negative. In other words, we again find evidence of Granger-causation running in both directions between capital and liquidity creation, which is negative.

Thus, choosing to exclude off-balance sheet items in the liquidity creation measures does not influence the relation between capital and liquidity creation. At first glance, this may not seem to be a surprising result, given the weakness of off-balance sheet items in the aggregate liquidity creation in the Czech banking industry, which was observed above. However, the low volume of off-balance sheet items at the aggregate level could obscure some strong differences across banks, where some have off-balance sheet items that make a significant contribution to their liquidity creation activity. Furthermore, this is an important result for emerging markets that commonly have a minor share of off-balance sheet items in banking activities.

In a second robustness check, we test whether our results are contingent on the period of study, which includes the financial crisis. Even if the impact of the economic downturn on the relation between capital and liquidity creation is unclear, this major economic event might have influenced the behavior of banks. In their analysis of the relation between capital and bank performance, Berger and Bouwman (2012) have shown that capital can affect banks differently during financial crises and normal periods. To address this issue, we rerun all of our estimations but only include the period from 2000 to June 2007. Tables 6 and 7 display the results with the broad and the narrow liquidity creation measures, respectively.

The results are very similar. With one exception, we again observe significantly negative coefficients for the sum of the lagged variables for capital when explaining liquidity creation and for liquidity creation when explaining capital. The exception concerns the specification with the broad measure of liquidity creation and the inclusion of macroeconomic control variables. In that case, the sum of the lagged variables for capital when explaining liquidity creation is negative but not significant (although with a p-value of 0.11). However, the three alternative specifications again show a significantly negative sum of lagged variables for capital. Thus, the finding of Grangercausation running in both directions between capital and liquidity creation is also observed when we omit the financial crisis period from our sample. Similarly, we do not see any clear differences in terms of the size of the effect of capital on liquidity and vice versa. This may be because, unlike banks in many European countries, the Czech banks were not strongly adversely affected by the crisis and maintained high capital adequacy at the pre-crisis levels (Czech National Bank, 2011).

In a third robustness check, we test whether our results are similar when using quarterly data rather than monthly data. Even if we were able to obtain a dataset including monthly data, the use of quarterly data might provide different results due to the periodicity of reporting and the longer time required for the impact of capital or liquidity creation on one another. Table 8 reports the results with the broad and the narrow measures of liquidity creation for the full sample and for the sample before the crisis. For the sake of brevity, we only report the sums of the lagged variables for capital and liquidity creation.

In a fourth robustness check, we use 12 lags of capital and liquidity creation because our baseline regressions use monthly data. This is to check whether the 4 lags that are used in Table 4 are too restrictive. We report the results in Table 9. The results are largely unchanged, as higher lags are typically not statistically significant.

Finally, in our fifth robustness check, we lag all control variables by one period, as they may affect capital and liquidity creation with a lag. The results are presented in Table 10. Again, they largely support our baseline findings.

We also analyze the sub-sample issues and examine whether the effect of capital on liquidity creation differs between small and large banks. Berger and Bouwman (2009) find that the negative effect from capital on liquidity creation is present only for small banks, and the effect is in fact positive for large banks (for medium banks it is insignificant). We divided our sample into two categories: the 8 largest banks (4 large and 4 medium banks according to the Czech National Bank classification) and small banks (18 small banks and 5 building societies). The correlation coefficients between liquidity and capital (as well as its lags) for both categories are negative but not significantly different from zero for the large banks category. The corresponding correlation coefficient for small banks is approximately -0.15, which is statistically significant at the 1% level. However, this coefficient is only -0.04 for large banks. The regression results (not reported) suggest that there is no effect of the capital on liquidity creation for large banks, but the results have to be taken with caution because the Arrelano-Bond estimator is designed for the case of "small T, large N" and we have only 8 banks in our large banks category (and T = 132). The results for small banks support our baseline findings. Ultimately, it seems that our sub-sample exercise results corroborate the findings of Berger and Bouwman (2009).

Overall, we find similar results even if the significance of the results is lower in some cases. The sum of the lagged variables for *Capital* when explaining *Liquidity Creation* is significantly negative in all estimations, which confirms our first finding. The sum of lagged variables for *Liquidity Creation* when explaining *Capital* is negative in all estimations, but it is not significant for the full sample. So the use of quarterly data rather than monthly data has a limited impact on our findings. It does not change our empirical support for the negative role of capital on liquidity creation, but it moderates our result on the negative role of liquidity creation on capital without contradicting it.

5. Conclusion

In this study, we investigate the relation between bank capital and liquidity creation by examining the causality of this link. A handful of recent papers have analyzed the impact of capital on liquidity creation, but they do so without considering the potential for reverse causality. We do so by performing Granger-causality tests on an exhaustive dataset of Czech banks, which makes a detailed computation of liquidity creation measures possible. This also allows us to provide evidence on the volume and evolution of liquidity creation in an emerging market in recent years. The analysis of liquidity creation by Czech banks shows a strong expansion in liquidity creation during the full period, which was slowed but not halted by the financial crisis. Large banks are the primary contributors to liquidity creation, which is in accord with observations of US banks.

We show that capital is found to negatively Granger-cause liquidity creation, which confirms the financial fragility hypothesis according to which greater capital hampers liquidity creation. However, we also observe that liquidity creation Granger-causes capital reduction. We thus support the view that there is a negative, bi-causal relation between capital and liquidity creation, which corroborates the importance of examining this causality. This reverse causality would also support the view that an optimal level of capital-liquidity creation combination might exist, however, this issue is left for further research.

Our findings have two policy implications. First, they suggest that the Basel III Accords may lead to reduced bank liquidity creation by introducing tighter capital requirements. As a result, these new rules may contribute to the creation of alternative economic difficulties by reducing liquidity creation, which can slow economic growth through reducing the amount of available financing. Second, our findings support the view that symmetrically greater liquidity creation may hamper bank solvency. In other words, enhanced liquidity creation can have some detrimental consequences.

Overall, our primary conclusion is that there is a trade-off between the benefits of financial stability induced by stronger capital requirements and those of greater liquidity creation. Therefore, any action in favor of one objective would deteriorate the other. The derived lesson is that regulatory authorities should take this antagonistic relation into account when proposing banking regulations.

We are fully aware that our findings may be dependent on our sample and may not be easily generalizable. However, the Basel III rules are planned to be implemented for a vast array of

countries, including that examined here and others that are similar. Hence our conclusions are of interest to bank regulatory authorities. In any case, to deepen our understanding of the relation between capital requirements and liquidity creation should occupy a high position on the bank regulation research agenda.
